Natural environmental change can both cause and maintain rarity. Cropper (1993) reported that some rare species, such as *Leptorhychos gatesii* in Australia, are observed only following natural fire. A riparian herb, *Collomia rawsoniana*, required periodic high and low streamflows to persist. Likewise, disruption of the natural hydrology of Lake Okeechobee, the largest lake in Florida, has led to the endangered listing of *Cucurbita okeechobeensis*. Land management decisions can obviously upset required disturbance patterns. Fire suppression activities and flood control will likely increase the rarity of such species.

The introduction of exotic grazers such as goats, pigs, rabbits, and sheep often leads to devastated native floras. For example, 47 of the 49 native plant species on St. Helena Island in the south Atlantic Ocean are now rare or threatened. The island was once dominated by beautiful forests of St. Helena ebony (*Trochetia melanoxylon*). Goats were introduced on the island in 1513, and the goat population skyrocketed by 1588. Goats ate ebony seedlings and humans used mature trees as fuel, so by 1810 the forests were destroyed and the ebony was extinct. About 260 naturalized exotic plant species were also introduced to the island (Davis *et al.*, 1986).

Introduced rabbits have greatly threatened *Acacia carnie* in arid western New South Wales, Australia (Cropper, 1993), and nearly decimated *Dudleya traskiae* (ironically called the Santa Barbara live-forever) on Santa Barbara Island off California (Benseler, 1987). Hawaii's beautiful Haleakala silversword (*Argyroxiphium sandwicense* ssp. *macrocephalum*), with a flower stalk up to 2 m tall, almost went extinct in the 1920s due to vandalism and grazing by introduced cattle and goats. Like many endangered plant species, several additional threats must be held at bay. A major effort in Hawaii is under way to

protect the habitat of the Haleakala silversword from invasive exotic plants (*Verbascum thapsus*, mullein; and *Pennisetum setaceum*, fountain grass) and the Argentine ant (*Iridomyrmex humilis*). The Argentine ant poses a significant threat to native pollinators of the silversword.

Competition from invasive exotic plant species may be a major contributor in the future to native plant endangerment. Large, nearly pure stands of exotic purple loosestrife (*Lythrum salicaria*) have directly influenced the endangered small spike-rush (*Eleocharis parvula*) in New York and Long's bulrush (*Scirpus longii*) in Massachusetts.

Consequences of Rarity

The most obvious consequence of rarity is extinction. Charles Darwin, like many naturalists of his time and since, recognized that rarity often preceded extinction. Small populations of sessile organisms are vulnerable to catastrophes. Landslides, fire, flooding, hurricanes, and other disturbances can simply wipe out populations. Small populations of vascular plants are also vulnerable to breeding problems from higher variability in breeding success caused by inbreeding. Inbreeding has been documented in several localized endemics such as *Limnanthes bakeri*, a vernal pool species in Mendocino County, California. In contrast, a common congener *Limnanthes douglassii* reproduces almost exclusively by cross-fertilization. *Stephanomeria malheurensis*, a plant species confined to one small hilltop in Burns, Oregon, is auto-fertile, whereas wide-spread congeners are not. Reproductive failure is not uncommon in sparse species. Lower genetic variation in small populations may also make them more vulnerable to rapid environmental change.

Not all small populations march rapidly toward extinction. Many rare plant populations can persist for centuries and millennia. Sparse populations can often avoid pathogens and herbivory. *Pinus ponderosa*, which may have been restricted to small refugia in Arizona and New Mexico at the end of the last Ice Age, has become the most widespread pine in the western United States; it now occurs from Mexico to Canada, and from California to Nebraska. Other small populations may speciate (form new species). For example, two species of *Ranunculus* in alpine areas of the North Island of New Zealand (*Ranunculus verticillata* and *Ranunculus insignis*) have given rise to *Ranunculus nivicola*.

Legal mandates to Protect Endangered Plants

Policy and Legal Mandates Throughout the World

The International Plant Protection Convention held in Rome in 1951 set forth recommendations for the protection and promotion of plant life throughout the world. Since then, the International Union for Conservation of Nature and Natural Resources (IUCN; now known as the World Conservation Union) has taken center stage in the protection of the world's flora. The IUCN Plant Red Book strongly defines "endangered species" as a species in danger of extinction and whose survival is unlikely if the causal factors (e.g., over-exploitation, extensive habitat destruction) continue operating, "including taxa whose numbers have been reduced to a critical level or

whose habitats have been so drastically reduced that they are deemed in immediate danger of extinction" (IUCN, 1998). It also identifies and tracks "vulnerable species" as those "believed likely to move into the endangered category in the near future if the causal factors continue operating." Finally, it tracks "rare species"—"taxa with small world populations that are not presently endangered or vulnerable, but are at risk." These IUCN classifications are determined by scientists and government officials around the world and classified species are not necessarily afforded legal protection after designation (Stermer, 1995).

Several countries have policies or legislation that protect endangered plant species. Following the Convention on International Trade in Endangered Species (CITES) of Wild Flora in 1973, 175 countries have agreed not to trade certain threatened species. Many countries augment these agreements with additional legislation. For example, the Mauritius National Plant Protection Legislation (the Plants Act of 1976) and the Forest and Reserves Act (1983) legally protects endangered species and habitats in the territories of Mauritius. Enforcement of endangered species laws and policies in many countries is generally considered to be well-intentioned but weak.

The United States Endangered Species Act

The intent of the U.S. Endangered Species Act of 1973 (16 USC1531-1543) is to prevent further decline and help restore endangered and threatened species and the habitats on which such species depend and to "provide a means whereby the ecosystems upon which endangered species and threatened species depend may be conserved" (Greenwalt and Gehringer, 1975). Thus, the Act recognizes the inseparable link between protecting a species, its habitat, and the surrounding ecosystem. The Act also provides broad-ranging protection for all species threatened with extinction in the "foreseeable future."

The Act makes the "taking" of endangered species anywhere within the United States a federal offense, requires federal agencies to use their existing authorities to conserve listed species, prohibits federal agencies from taking actions that may jeopardize a species' existence, provides a formal structure for listing endangered species, and provides a means for citizens to bring suit against any federal agency for failure to meet its obligations under the Act (Flather *et al.*, 1994).

Ayensu and DeFilipps (1978) noted that a species may be rare at the edge of its range, but not endangered or threatened as a whole. In determining national endangered, threatened, and extinction status, the total range and abundance of the species must be considered. However, states may further protect a species threatened with extirpation. Still, the cost of protecting individual species and habitats against multiple stresses is high, and the reality is that enforcement on public and private lands is generally weak.

Selected Examples of Endangered Plants

Coleus Forskohlii (Willdenow)

Coleus forskohlii, a 40-cm-tall, rare herb, is found in the Yunnan Province of China, Bhutan, India, Nepal, Sri Lanka, and Africa at

about 2300 m on steep slopes (Figure 3). Compounds extracted from the roots have long been a Hindu Ayurvedic traditional medicine. Rampant collection has increased the rarity of this species. A German pharmaceutical company holds at least six U.S. patents for use of the plant as treatments for high blood pressure, cardiovascular disease, colic, respiratory problems, insomnia, painful urination, and convulsions. This is sometimes referred to as "biopiracy," when the intellectual property of indigenous peoples is appropriated and used by foreign companies to develop and patent commercial products.

Fitzroya Cupressoides

Fitzroya cupressoides is an ancient tree species in southern Chile (Figure 4). Only 5% of the world's temperate forests are in the Southern Hemisphere, and one-third of the threatened temperate forests occur in Chile. The highest biodiversity in any

temperate forest is also found in Chile. These forests are remarkably productive, with some of the world's largest concentrations of biomass. Old-growth *F. cupressoides* trees often reach 4–5 m in diameter and may live for 4000 years. One-third of Chile's forests were burned or cleared by 1955. Some *Fitzroya* populations are protected in nature reserves, but most of the forests containing this species are privately owned.

Sarracenia Rubra ssp.

Sarracenia Rubra ssp. *Alabamensis*

The Alabama canebrake pitcher-plant is a carnivorous plant with maroon flowers on 0.6-m stalks originating from rhizomes (underground roots; Figure 5). It is found in sandy and gravelly bogs, seeps, springs, and swamps, and flowers from late April to early June. *Sarracenia rubra* ssp. *alabamensis* is restricted to only 12 localized sites in a three-county area in

Coleus forskohlii root

The root of *Coleus forskohlii* is the only source of the biologically active compound Forskolin. This ancient medicinal herb has been re-discovered by modern pharmaceutical researchers who have patented uses of the plant. *Coleus forskohlii* grows in the Yunnan Province of China, and in Bhutan, India, Nepal, Sri Lanka, and Africa.

Figure 3 *Coleus forskohlii*.

Figure 4 *Fitzroya cupressoides*. (Photograph courtesy of Dr. T T Veblen.)

central Alabama. Four of the 12 sites have 70–300 plants each, and half the populations have 2–20 plants each. Much of the original habitat (16 other sites) has been modified or destroyed by agriculture and construction of farm ponds in boggy areas. Fire exclusion, gravel mining, and invasive plants pose additional threats. Several populations have also been lost or degraded by plant collectors.

Encephalartos Longifolius

South African cycads are ancient gymnosperms and the most primitive living seed-bearing plants on Earth (Figure 6). They flourished 50–60 million years ago and provided forage for dinosaurs before then. In South Africa, all 40 cycad species are endangered, and some species are extinct in the wild. The thick-trunked plants with rigid spiked leaves grow very slowly; some species take 100 years to grow 1 m. Habitat loss and competition from invasive exotic plant species are often cited as causes of rarity, but illegal collecting is also a major problem. South Africa has some of the world's strictest laws controlling cycad theft, but the thefts continue. Some cycads now have implanted microchips for identification and tracking purposes in an effort to curb poaching.

Pterostylis Truncata

Brittle greenwood is a ground-dwelling orchid that emerges in the fall with large, squat flowers (Figure 7). It is a clonal plant that can regenerate vegetatively, and its flowers can be pollinated by flies or fungus gnats. *Pterostylis truncata* is found in only three locations in south-central New South Wales, Australia. One of the populations is threatened by introduced European rabbits (*Oryctolagus cuniculus*), feral goats (*Capra hircus*), and eastern gray kangaroos (*Macropus giganteus*). An additional recent threat comes from the highly invasive weed *Chrysanthemoides monifilera*. The second population is on private land, where it is potentially threatened by kangaroos and rabbits. The third population occurs in a forest reserve; here it is threatened from trampling by orchid enthusiasts, weed invasions, and bird predation.

Species-Environmental Matching Models

A new tool for rare and threatened plant species detection and conservation is the use of species-environmental matching models (Phillips *et al.*, 2006). These models use species

The Alabama canebrake pitcher-plant (*Sarracenia rubra* ssp. *alabamensis*) is an endangered, carnivorous plant. It is restricted to only 12 sites in central Alabama. Many factors have contributed to the listing of this plant as endangered, including habitat destruction, fire suppression, and the introduction of non-native plants.

Sarracenia rubra ssp. *alabamensis*

Figure 5 *Sarracenia rubra* ssp. *alabamensis*.

locations, with dozens of geographic information themes (e.g., climate factors, soils, topography, land use, vegetation) to model habitat suitability of a species. Kumar and Stohlgren (2009) showed the utility of the models for a threatened and endangered tree *Canacomyrica monticola* in New Caledonia (Figure 8). Only 11 locations were known (De Lang *et al.*, 2010). Maximum entropy model or Maxent (Phillips *et al.*, 2006), one of the species-environmental matching models, had a 91% success rate. Model results were successfully used to find *C. monticola*'s new populations at 12th location in southern New Caledonia (Figure 8). This approach is quite promising for predicting suitable habitat for threatened and endangered species and locating new populations or artificial introduction sites.

Implications

Reducing the rate of habitat loss around the world will be difficult. Between 1980 and 1990, species-rich tropical forests were cleared at the rate of 6.3 million ha year⁻¹ (15.4 million acres year⁻¹), or 0.8% of the forest per year (Heywood, 1995).

Deforestation causes habitat loss, habitat fragmentation, and edge effects at the boundaries, so the effects are greater than indicated by the actual deforested area. Large areas will be lost to urbanization and agriculture. Many dry grasslands in Germany have been converted to range and arable land in recent decades, making it more difficult to protect the nation's 164 threatened plant species (Heywood, 1995). Thus, saving critical habitats throughout the world is seen as increasingly important and extremely urgent.

A species-by-species approach to rare plant conservation is expensive and difficult. However, the unstated assumption of the habitat preservation approach is that species are inseparably linked to habitats, which in turn are stable and predictable. Yet because habitats may be neither stable nor predictable (Flather *et al.*, 1994), both species and habitats must be monitored to protect endangered plants and animals. In Australia, management techniques to protect critical habitats and species include: burning or slashing overgrown vegetation, removal of weeds, removal of grazing animals, hand pollination of selected species, propagation and seed storage, reintroduction into restored habitats, and quarantine to reduce the threat of introduced pathogens (Cropper, 1993).

Encephalartos species with male cones.

Encephalartos is the second largest genus in the Cycad genera. All *Encephalartos* are endemic to the African continent, with most in xeric habitats. Natural populations of *Encephalartos* suffer intense pressure from plant collectors.

Figure 6 *Encephalartos longifolius*. (Photograph courtesy of Dr. D A Steingraeber.)

Pterostylis truncata

Brittle greenhood (*Pterostylis truncata*) is a clonal orchid, found in New South Wales and Victoria, Australia. Causes of this orchid's decline include overgrazing by feral goats and European rabbits and the introduction of a highly invasive weed into its habitat.

Figure 7 *Pterostylis truncata*.

Less than 10% of named plant species have been analyzed for medicinal or nutritional properties (Stermer, 1995). Nonetheless, 25–40% of all drug prescriptions in the United States contain plant ingredients (Durant and Saito, 1985), and many of these ingredients cannot be synthetically made. About 80% of people in developing countries use traditional medicines. As more and more plant species go extinct, so may

our chances to find the next heart medicine (e.g., *Digitalis*; foxglove) or treatment for childhood leukemia (from *Catharanthus roseus*; the rosy periwinkle).

To improve the effectiveness of biodiversity conservation, increased emphasis is needed on systematic surveys and monitoring. Many species may be classified as rare owing to poor surveys, as evidenced by the rate of species discoveries.

Figure 8 Potential suitable habitat for *Canacomyrica monticola* on Grande Terra, the main island of New Caledonia.

Since 1970, for example, one botanist has discovered 55 new plant species in Utah, and more than 80 species have been named since 1970 (Durant and Saito, 1985). Botanists searching the well-studied Rocky Mountain National Park in Colorado added more than 100 species to the Park's plant checklist between 1987 and 1992 (Stohlgren *et al.*, 1997). On average, one or two native plant species are added to the flora of New York each year. The Nature Conservancy and Natural Heritage Programs have found that plant surveys often show that many plant species are more common than previously believed. For example, several populations of rare orchids have been found in Australia after intensive searches. Systematic surveys of plants and rare habitats are badly needed.

The preservation of intact ecosystems may be the most promising way to protect endangered plants. It is now widely understood that maintaining natural disturbance regimes, such as fire and flooding, is important for many rare species (Cropper, 1993), and that preserving the habitat around rare plant locations is vitally important. However, subtle assaults to endangered species may include the use of fertilizers, herbicides, and insecticides that may reduce plant pollinators, invasive plant species that may out-compete the endangered plants, and introduced foreign diseases, insects, or domesticated/feral animals that may further endanger plants. Where habitat loss and degradation have been significant, habitat restoration efforts and species re-introductions are needed.

Cultivation, the last resort for endangered plants, may become necessary in some cases to preserve genetic variation. *Franklinia* (*Franklinia alata*) is a familiar example. *Franklinia* is a small tree that was restricted naturally to the Altamaha River basin in southeastern Georgia. Now extirpated in the wild, the species survives as an ornamental throughout the eastern United States. In Australia, 1053 of 3329 rare and

threatened plant species are found only in botanical gardens, and 515 plant species are held in only one collection (Cropper, 1993). Several botanical gardens in the United States have active programs to study, collect, and grow rare and endangered plants from all over the world. However, duplicate and more complete collections are needed in most countries, and such a system of collections should not be viewed as a substitute for preserving native habitats and ecosystems.

Some plants have appeared to bounce back from extinction. Mountain golden heather (*Hudsonia montana*) was described by Thomas Nuttall in 1818 in North Carolina, and was thought to be extinct in the 1960s. About 2000 individuals were found in the Blue Ridge Mountains around 1990 (Burton, 1991). Running buffalo clover (*Trifolium stoloniferum*) was also believed to be extinct, but it was rediscovered in 1983 in West Virginia and later discovered in four other states. Also in 1983, *Lomatium peckianum* was rediscovered in Oregon after "disappearing" for over 50 years. In 1985, one species of clover (*Trifolium microcephalum*) that had not been seen since the Lewis and Clark expedition in 1805–1806 was rediscovered. Such stories are not uncommon. Eleven plant species in New York have been "rediscovered" in the past 10 years. However, expecting miraculous rediscoveries for many long-lost species is probably unrealistic.

This article has focused on endangered vascular plants. However, many nonvascular plants are similarly threatened. For example, > 50% of the mushrooms in Europe are listed as endangered or threatened in at least one country. Species that were once common, such as *Hydnum repandum*, have been extirpated in some countries. Over-collection of the lichen *Gymnoderma lineare* in the Great Smoky Mountains National Park has led to its recommendation for listing. Air pollution and acid deposition are known to adversely affect many

nonvascular plant species. The assessment of endangered plants cannot be done without assessing the interacting species (e.g., pollinators and symbiotic fungi) and the ecological processes that affect complexes of rare and common species.

Understanding the causes and consequences of rarity also requires a comprehensive knowledge of biology, evolutionary and recent history, and species demography. Often, the causes of population decline may be elusive. For example, *Torreya taxifolia*, the Florida torreya, is a narrowly restricted endemic conifer that has suffered catastrophic declines since the 1950s. Pathologists and ecologists have studied the problem relentlessly and found no obvious cause for the decline. There are now fewer than 1500 trees in the wild, with no solution in sight. In many cases, careful field and laboratory experiments may be necessary to isolate the causes of rarity.

It is equally important to increase public awareness about the ecology of rarity and the economic and social consequences of losing our endangered plants. In the end, protecting endangered species and biodiversity is a question of ethics and values. Endangered plants are best viewed as valuable resources and inherently valuable species with which we share the Earth.

Acknowledgments

April Owen and Lisa Schell assisted with the literature review and graphics. Curtis Flather provided information and Figure 2. Geneva Chong, April Owen, and Lisa Schell provided helpful comments on an earlier version of the manuscript. To all I am grateful.

Glossary

Air pollution Lowering of air quality due to release of toxic materials by factories, automobiles, fires, and other human activities.

Disease Infections by parasitic organisms that can cause weakness, decreased reproduction, and death.

Exotic species Species that occurs outside its natural range owing directly or indirectly to human activity.

Global climate change Current and predicted changes in global temperature, rainfall, and other aspects of climate due to increased human production of carbon dioxide and other greenhouse gases.

Habitat fragmentation Process by which a continuous area of habitat is divided into two or more fragments by roads, farms, fences, logging, and other human activities.

Overexploitation Harvesting of a natural resource, such as fish or timber, at a rate more rapidly than it can be naturally replenished.

Water pollution Lowering of water quality due to input of sewage, pesticides, agricultural runoff, and industrial wastes that can harm aquatic plants and animals.

If species and natural communities are adapted to local environmental conditions, why should they be faced with extinction? Shouldn't species and communities be able to persist in the same places that they have for thousands of years? Why are species going extinct now? The answers to these questions have become clear in recent decades: Massive disturbances caused by people have altered, degraded, and destroyed the natural landscape on a vast scale, drastically upsetting the balance between natural rates of speciation and extinction. Extinction rates have been increasing since 1650, and we are now in the midst of a sixth mass extinction episode, this one caused by human activities rather than by a natural disaster. The process of evolution will eventually create new species, but this will take thousands, if not millions, of years. And numerous unique species such as pandas, elephants, and cheetahs will be gone forever.

An Expanding Human Population

The major human-induced threats to biological diversity are habitat destruction, habitat fragmentation, habitat degradation (including air and water pollution), overexploitation of species for human use, exotic species introductions, and increased spread of disease (Figure 1). Most threatened species face at least two or more of these threats, speeding their way toward extinction and hindering conservation efforts. Typically, these threats develop so rapidly and on such a large scale that species are not able to adapt genetically to the changes or to disperse to a more hospitable location. These threats will continue to increase as the human population grows, development and overexploitation continue, remaining natural habitats disappear, and as global climate continues to change.

Figure 1 Habitat loss and degradation are the greatest threats to the world's species, followed by overexploitation. Groups of species face different threats; birds are more threatened by invasive species, whereas amphibians are more affected by disease and pollution. Percentages add up to more than 100% because species often face multiple threats. Reproduced with permission from Primack RB (2010) *Essentials of Conservation Biology*, 5th edn. Sunderland, MA: Sinauer Associates; based on data from the International Union for Conservation of Nature (IUCN), 2004.

These threats to biological diversity are all caused by an ever-increasing use of the world's natural resources by an expanding human population. In Europe, only 15% of the land area remains unmodified by human activities, and the amount of many specific habitat types remaining is below 10%. The greatest destruction of biological communities has occurred during the last 150 years, during which the human population exploded from 1 billion in 1850 to 2 billion in 1930, and to 6 billion in 2001. World population will reach an estimated 7 billion by the end of 2011 and 10 billion by 2050 (Figure 2). Birth rates have remained high whereas mortality rates have declined, particularly during the last century, as a result of both medical discoveries (specifically, disease control) and more reliable food supplies. Population growth has slowed in industrialized countries but is still high in many areas of tropical Africa, Latin America, and Asia, where the greatest biological diversity is also found. The increase in human population is predicted to cause an additional 14% of bird and mammal species to be threatened with extinction by 2050.

People use natural resources, such as fuelwood, wild meat, and wild plants, and convert vast amounts of natural habitat for agricultural and residential purposes. Agricultural systems now occupy one-fourth of the Earth's land surface. Because some degree of resource use is inevitable, population growth is partially responsible for the loss of biological diversity. All else being equal, more people equals less biodiversity. Some scientists have argued strongly that controlling human population

Figure 2 The human population in 2011 is almost 7 billion. The World Resources Institute estimates current annual population growth at 1.1%, but even this modest growth rate will add more than 72 million people to the planet in the next year. This number will escalate each year as the increase is compounded. Reproduced from Primack RB (2010) *Essentials of Conservation Biology*, 5th edn. Sunderland, MA: Sinauer Associates; based on data from the US Census Bureau.

size is the key to protecting biological diversity; however, overconsumption of resources is also responsible for habitat destruction and species extinctions. The rise of industrial capitalism and materialistic modern societies has greatly accelerated demands for natural resources, particularly in developed countries. Inefficient and wasteful use and overconsumption of natural resources are major causes for the decline in biological diversity. For example, if fewer paper products were used and more paper was recycled, then there would be less need to cut down forests to manufacture new paper.

Unequal Use of Natural Resources

In many countries there is extreme inequality in the distribution of wealth, with a small percentage of the population controlling, owning, and consuming much of the wealth and natural resources such as good farmland, livestock, and timber resources. In many developing countries, large landowners and business interests commonly force local farmers off their land, a pattern often reinforced by the government, the police, and the army. Political instability, lawlessness, and war also displace farmers into remote, undeveloped areas where they feel safer. Most practice shifting cultivation, a form of agriculture involving cutting down forest, burning the plant material, and planting crops in the nutrient-rich ash, because it is the simplest way to make a living when they may be obliged to move again within a short time. Landless farmers and their families often exploit natural resources in their surroundings just to stay alive; often these resources are components of species-rich biological communities.

The unequal use of natural resources worldwide also drives the destruction of biological diversity in species-rich tropical areas. People in industrialized countries (and the wealthy minority in developing countries) consume a disproportionate share of the world's energy, minerals, wood products, and food. Each year, the US, which has 5% of the world's population, consumes roughly 25% of the world's natural resources. The average US citizen annually uses 23 times more energy and 79 times more paper products than does the average citizen of India. The excessive consumption of wealthy individuals, cities, and countries thus leaves a large ecological footprint, meaning that a wide area of the world must supply their needs. This unsustainable resource consumption will cause massive environmental disruption if adopted by the expanding middle class in the developing world.

Large-Scale Development Projects

In many cases, the factors causing habitat destruction, particularly in the developing world, are the large industrial and commercial activities associated with a global economy – mining, cattle ranching, commercial fishing, forestry, plantation agriculture, manufacturing, and dam construction – and initiated with the goal of making a profit. Many of these projects are funded by national governments and international development banks and are touted as sources of jobs, commodities, and tax revenues. Others are initiated and funded by large multinational corporations. However, this exploitation of natural resources often is neither efficient nor cost-effective because

the emphasis is on short-term gain, often at the expense of long-term sustainability and generally with little regard for the local people who depend on the resources.

Habitat Destruction

Increasing human populations and their activities use even greater proportions of the world's terrestrial and marine environments and associated natural resources, resulting in the inevitable destruction of genetic variation, species, habitats, and ecosystem processes.

Habitat Loss

Habitat loss is the primary threat to the majority of vertebrate species currently facing extinction, a generalization that is certain to be true for threatened invertebrates, plants, and fungi as well. In many countries of the world, particularly on islands and in locations where human population density is high, most of the original habitat has been destroyed. Agriculture, commercial development, water projects, livestock grazing, pollution, infrastructure and roads, logging, and outdoor recreation threaten habitats of endangered species. More than 50% of the habitat has been destroyed in 49 of 61 Old World tropical countries. In tropical Asia, 65% of the primary forest habitat has been lost, with particularly high rates of destruction reported for Bangladesh (96%), Sri Lanka (86%), India (78%), and Vietnam (76%). Similarly, sub-Saharan Africa has lost about 65% of its forests, with losses most severe in Gambia (89%), Ghana (82%), and Rwanda (80%). Two biologically rich nations, Zimbabwe and the Democratic Republic of Congo (formerly Zaire), are relatively better off with about half of their forests remaining, although

it is too soon to say how the recent civil war in the latter country has harmed its wildlife population. In the Mediterranean region which has been densely populated for thousands of years, only 10% of the original forest remains. Present rates of deforestation vary considerably among countries, with particularly high annual rates of 1.5–2% for tropical countries such as Vietnam, Côte d'Ivoire, Mexico, Paraguay, and Costa Rica.

For many important species, the majority of habitat in their original range have been destroyed, and a very little of their remaining habitat is protected. For certain Asian primates, such as the Javan gibbon, more than 95% of the original habitat has been destroyed. The orangutan, a great ape that lives in Sumatra and Borneo, has lost 63% of its habitat and is protected in only 2% of its range. Such habitat losses inevitably lead to extinctions.

Rain Forest Loss

Tropical rain forests occupy just 7% of the Earth's land surface but are estimated to contain over 50% of its species. Their destruction has therefore come to be synonymous with the loss of species. These evergreen to partly evergreen forests occur in frost-free areas below about 1800 m in altitude and experience at least 100 mm (4 in) of rain per month in most years. Rain forests are characterized by great species richness and complex species interactions and specializations unparalleled in any other community. Based on current patterns of rainfall and temperature, the original extent of tropical rain forests and related moist forests has been estimated at 16 million km². Only 11.5 million km² remained in 1990, and an additional 2.4% was lost between 2000 and 2005 (Figure 3).

Most rain forest destruction results from small-scale agriculture and firewood collection, mostly by poor farmers who have moved to forest areas to practice shifting cultivation out of desperation and poverty. Other major causes include

Figure 3 This Fuller projection, which distorts the sizes and shapes of continents less than typical maps do, shows the current extent of tropical forests and areas that have been cleared. Note the extensive amount of deforested land in northern and southeastern South America, India, Southeast Asia, Madagascar, and western Africa. Reproduced from Primack RB (2010) *Essentials of Conservation Biology*, 5th edn. Sunderland, MA: Sinauer Associates, and Pimm SL and Jenkins C (2005) Sustaining the variety of life. *Scientific American* 293(33): 66–73, with permission from Sinauer Associates.

clearing for commercial logging, cattle ranches, cash crop plantations (oil palm, cocoa, rubber, etc.), road building, and mining. At the current rate of destruction (approximately 140,000 km² per year), there will be no large blocks of tropical forest left after the year 2040, except in the relatively small national parks and protected areas and a few remote areas of the Brazilian Amazon, central Africa, and the islands of Borneo and Papua New Guinea (**Figure 4**). The situation is actually grimmer than these projections indicate because the world's population is still increasing, and poverty is rising in many developing tropical countries, putting ever-greater demands on the dwindling supply of rain forest.

Other Threatened Habitats

The plight of the tropical rain forests is perhaps the most widely publicized case of habitat destruction, but other habitats are also in grave danger.

Tropical Deciduous Forests

Tropical deciduous forests contain many species and in some places rival the diversity of the tropical rain forests. The land occupied by tropical deciduous forests is more suitable for agriculture and cattle ranching than the land occupied by tropical rain forests. Moderate seasonal rainfall, in the range of 250–2000 mm per year, allows nutrients to be retained in the soil, where they can be taken up by plants. These forests are also easier to clear and burn than rain forests. Consequently, human population density is five times greater in dry forest areas of Central America than in adjacent rain forests. Today, the Pacific coast of Central America has less than 2% of its original extent of deciduous dry forest remaining, and many species have been lost or are threatened with extinction.

Grasslands

Temperate grasslands have also been almost completely destroyed by human activity, with a consequent loss of species. It is relatively easy to convert large areas of grassland to farmland and cattle ranches. Illinois and Indiana, for example, originally contained 15 million ha (37 million acres) of tall-grass prairie, but now only 1400 ha (3500 acres) of this habitat – one-ten-thousandth of the original area – remain undisturbed. The rest have been converted to farmland, and the remaining area of prairie is fragmented and widely scattered across the landscape. Though widespread efforts to restore prairies in many areas of the world are underway and should be encouraged, it is impossible to bring back species that have already been lost.

Wetlands and Aquatic Habitats

Wetlands are critical habitats for fish, aquatic invertebrates, aquatic plants, and birds. They also provide services to humans such as flood control, drinking water, and power production. Wetlands are often filled in or drained for development, or they are altered by channelization of watercourses, dams, chemical pollution, and siltation. This habitat destruction increases extinction risk for aquatic species, especially one with limited distributions. During the last 200 years, over half of the wetlands in the US have been destroyed. The

Florida Everglades, a premiere wildlife refuge, is now on the verge of ecological collapse. Approximately 40–50% of the freshwater snail species in the southeastern US are either extinct or endangered. In California's San Diego County, more than 97% of the vernal pools, which support a unique endemic biota, have been destroyed. Furthermore, massive development projects in other parts of the industrialized world, such as the Three Gorges Dam in China, are destroying aquatic ecosystems on an unprecedented scale.

Mangroves

Mangrove forests are among the most important wetland communities in tropical areas. Composed of species that are among the few saltwater-tolerant woody plants, mangrove forests occupy coastal areas with saline or brackish water, typically where there are muddy bottoms. Such habitats are similar to salt marshes in the temperate zone. Mangroves are extremely important breeding grounds and feeding areas for shrimp and fish. They also reduce storm damage. Despite their great economic value, mangroves are often harvested for timber and charcoal production and cleared for development. In recent years, mangroves have been increasingly cleared for rice cultivation and commercial shrimp hatcheries, particularly in Southeast Asia, where as much as 15% of the mangrove area have been removed for aquaculture. Over 35% of the world's mangrove ecosystems have been destroyed, and 40% of vertebrates endemic to mangroves are threatened with extinction.

Coral Reefs

Tropical coral reefs contain an estimated one-third of the ocean's fish species in only 1% of its surface area. Already 20% of all coral reefs have been destroyed, and an additional 20% have been degraded. The most severe destruction is taking place in the Philippines, where a staggering 90% of reefs are dead or dying. The main culprits are pollution, which either kills the coral directly or allows excessive growth of algae; sedimentation following the removal of forests; overharvesting of fish, clams, and other animals; climate change; invasive species; and, finally, fishermen blasting with dynamite and releasing cyanide and other poisons to collect the few remaining living creatures.

Extensive loss of coral reefs is expected within the next 40 years in tropical East Asia, around Madagascar and East Africa, and throughout the Caribbean (**Figure 4**). In the Caribbean, a combination of overfishing, hurricane damage, water pollution, and disease is responsible for a dramatic decline of a large proportion of the coral reefs and their replacement by fleshy macroalgae. Elkhorn and staghorn corals, which were formerly common and gave structure to the community, have already become rare in many locations.

Desertification

Many biological communities in seasonally dry climates are degraded into man-made deserts by human activities, a process known as desertification. These communities include tropical grasslands, scrub, and deciduous forests, as well as temperate shrublands, such as those found in the Mediterranean region, southwestern Australia, South Africa, central

Figure 4 Extensive areas of coral will be damaged or destroyed by human activity over the next 40 years unless conservation measures can be implemented. Reproduced from Primack RB (2010) *Essentials of Conservation Biology*, 5th edn. Sunderland, MA: Sinauer Associates, and Bryant D, Burke L, McManus J, and Spalding M (1998) *Reefs at Risk: A Map-Based Indicator of Threats to the World's Coral Reefs*. Washington, DC: World Resources Institute, with permission from Sinauer Associates.

Chile, and California. Approximately 10–20% of these dry areas are degraded, with more than 25% of the productive capacity of their plant growth lost. Although these areas may initially support agriculture, repeated cultivation, especially during dry and windy years, often leads to erosion and loss of the soil's capacity to retain water. Land may also be chronically overgrazed by domestic livestock, such as cattle, sheep, and goats, and woody plants may be cut down for fuel. The result is a progressive and largely irreversible degradation of the biological community and loss of soil cover. Ultimately, the original species are lost, and the region takes the appearance of a desert. The process of desertification is most severe in the Sahel region of Africa, which is estimated to have 2.5 times more people than the land can sustainably support.

Habitat Fragmentation

In addition to outright destruction, habitats that formerly occupied wide, unbroken areas are now often divided into two or more fragments by roads, fields, farms, houses, industries, fences, power lines, and a broad range of other human constructs and activities. Fragmentation almost always occurs during a severe reduction in habitat area, but it can also occur when area is reduced to only a minor degree wherein the original habitat is divided by railroads, canals, fences, oil pipelines, fire lanes, or other barriers to the free movement of species. The island model of biogeography is applicable to this situation: the fragments, often isolated from one another by a highly modified or degraded landscape (Figure 5), may be considered as habitat islands in an inhospitable human-dominated sea. Fragments differ from the original habitat in three important ways: (1) fragments have a greater amount of edge for the area of habitat, (2) the center of each habitat fragment is closer to an edge, and (3) a formerly continuous habitat hosting large populations is divided into pieces, with smaller populations.

Figure 5 The forests of tropical Asia have experienced massive deforestation and fragmentation in recent decades. Intense habitat destruction in Sumatra, a large island of Indonesia, has occurred over the past 100 years and was predicted to continue through 2010. Reproduced from Primack RB (2010) *Essentials of Conservation Biology*, 5th edn. Sunderland, MA: Sinauer Associates, and Bradshaw CJA, Sodhi NS, and Brook BW (2009) Tropical turmoil: A biodiversity tragedy in progress. *Frontiers in Ecology and the Environment* 7: 79–87, with permission from Sinauer Associates.

Barriers to Dispersal

Fragmentation may limit a species' potential for dispersal and colonization. Many bird, mammal, and insect species of the forest interior will not cross even very short distances of open area, partly due to the high risk of predation in edge and open habitats. Habitat fragmentation also creates barriers to normal dispersal and the colonization processes. In an undisturbed environment, seeds, spores, and animals move passively and actively across the landscape. When they arrive in a suitable but unoccupied area, a new population begins to develop at that site. Over time, population of a species may build up and go extinct on a local scale as the species disperses from one suitable site to another and the biological community undergoes succession. Because habitat fragmentation limits this dispersal, the species may gradually die out.

Habitat fragmentation also reduces the foraging ability of individual animals. Many species, either as individuals or

social groups, need to move freely across the landscape to feed on widely scattered resources. However, fences and other barriers may prevent the natural migration of animals, such as wildebeest or bison, forcing them to overgraze an unsuitable habitat, eventually leading to starvation and habitat degradation. Barriers to dispersal can restrict the ability of widely scattered species to find mates, causing a loss of reproductive potential for many animal species. Plants also may reduce seed production if butterflies and bees are less able to migrate among habitat fragments to pollinate flowers. Finally, dividing a formerly large population into several smaller ones means that the new, smaller populations will be more vulnerable to genetic and other problems associated with small populations, increasing their risk of extinction.

Edge Effects

Habitat fragmentation often changes the microenvironment at the fragment edge, resulting in increased light levels, higher daytime temperatures, higher wind speeds, and lower humidity. Each of these edge effects can have a significant impact on the vitality and composition of the species in the fragment. Species that are sensitive to humidity such as amphibians, many insects, and herbaceous plants, will be eliminated from the forest fragments. Also, increased wind, lower humidity, and higher daytime temperatures make fires more likely in forest fragments. Fires may spread into habitat fragments from nearby agricultural fields that are being burned regularly, as in sugarcane harvesting, or from the irregular activities of farmers practicing shifting cultivation. In the process, many species will be eliminated.

Interspecific Interactions

Habitat fragmentation also increases the vulnerability of the fragment to invasion by exotic and native pest species. Omnivorous native animals, such as raccoons, skunks, and blue jays, and introduced animals, such as rats, may increase in population size along forest edges, where they can eat food found in both undisturbed and disturbed habitats. These aggressive feeders may seek out the nests of interior forest birds, often preventing successful reproduction of many bird species hundreds of meters from the nearest forest edge. Domestic cats can also be important predators in settled areas with fragmented landscapes. Weedy plant species and exotic herbivores can eliminate native plant species along the edges of fragments, and disease can similarly spread into the interior of habitat fragments.

Habitat Degradation and Pollution

Communities and species in a habitat can be profoundly affected by human activities, even if the habitat itself is not. Biological communities can be damaged and species driven locally or globally extinct by external factors that do not change the structure of dominant plants in the community, so that the damage is not immediately apparent. For example, in temperate deciduous forests, frequent and uncontrolled

ground fires might not kill the mature trees, but the rich perennial wildflower community and insect fauna on the forest floor would gradually become impoverished. Keeping too many cattle in grassland communities gradually changes the biological community, often eliminating many native species and favoring exotic species that can tolerate grazing. Boat hulls, anchors, and divers' flippers can crush fragile species on coral reefs. Trawling destroys 15 million km² of seafloor communities each year, 150 times greater than the area of forest cleared annually. The subtlest form of environmental degradation is pollution, commonly caused by pesticides, sewage, fertilizer runoff from agricultural fields, industrial chemicals, and wastes, emissions from factories and cars, and sediment deposits from eroded hillsides. The general effects of pollution on water quality, air quality, and even global climate are causes for great concern, not only because of the threats to biological diversity, but also because of their effects on human health.

Pesticides

The dangers of pesticides were brought to world's attention in 1962 by Rachel Carson's influential book *Silent Spring*. Carson described a process, now known as biomagnification, through which (dichlorodiphenyltrichloroethane DDT) and other organochlorine pesticides become concentrated as they ascend the food chain. These pesticides, at that time widely used to kill agricultural pests and mosquito larvae were harming wildlife populations, especially birds that ate large amounts of insects, fish, or other animals exposed to DDT and its byproducts. Birds with high levels of pesticides in their tissues, particularly raptors such as hawks and eagles, became weak and tended to lay eggs with abnormally thin shells that cracked during incubation. As a result of failure to raise young and the outright death of many adults, populations of these birds showed dramatic declines throughout the world.

Recognition of this situation in the 1970s led many industrialized countries to ban the use of DDT and other chemically related pesticides. The ban eventually allowed the partial recovery of many bird populations, most notably peregrine falcons (*Falco peregrinus*), ospreys (*Pandion haliaetus*), and bald eagles (*Haliaeetus leucocephalus*). Nevertheless, the continuing massive use of pesticides and DDT in other countries is still a cause for concern, not only for endangered animal species, but also for the potential long-term effects on people, particularly the workers who handle these chemicals in the field and the consumers of agricultural products treated with these chemicals. These chemicals are widely dispersed in the air and water and are persistent in the environment even in countries where their use has been outlawed.

Water Pollution

Water pollution destroys important food sources and contaminates drinking water with chemicals that can cause immediate and long-term harm to human health. Water pollution also often severely damages aquatic ecosystems. Rivers, lakes, and oceans are used as open sewers for industrial and residential waste. Pesticides, herbicides, oil products, heavy

metals (such as mercury, lead, and zinc), detergents, and industrial wastes can kill aquatic organisms outright or make the environment so inhospitable that species can no longer thrive. For instance, water pollution is a threat to 90% of the endangered fishes and freshwater mussels in the US.

Unlike terrestrial dumps, whose effects are primarily local, toxic wastes in aquatic environments diffuse over a wide area. Many aquatic environments are naturally low in essential minerals, such as nitrates and phosphates, and aquatic species have adapted to the natural scarcity of minerals by developing the ability to process large volumes of water and to concentrate these minerals. When these species process polluted water, they concentrate toxic chemicals along with the essential minerals, which can eventually poison the plant or animal. Species that feed on these aquatic species then ingest these high concentrations of toxic chemicals.

Essential minerals that are beneficial to plant and animal life can become harmful pollutants at higher levels. Human sewage, agricultural fertilizers, detergents, and industrial processes often release large amounts of nitrates and phosphates into aquatic systems, causing cultural eutrophication. For instance, humans release as much nitrate into the environment as do all natural processes, and this input is expected to increase in tandem with the increasing human population. Even small amounts of these nutrients can stimulate plant and animal growth, and high concentrations often result in thick blooms of algae at the surface of ponds, lakes, and coastal areas. These algal blooms may be so dense that they out-compete with other plankton species and shade out bottom-dwelling plant species. As the algal mat becomes thicker, its lower layers die and sink. Bacteria and fungi then decompose the dying algae, absorbing all the oxygen in the water. Without oxygen, much of the remaining animal life dies off, sometimes visibly in the form of masses of dead fish floating on the water surface. The result is a greatly impoverished and simplified community consisting of only those species tolerant of polluted water and low oxygen levels. The spreading dead zone where the Mississippi River enters the Gulf of Mexico is an example of the direct consequences of water pollution. Such dead zones are increasing in number and size around the world as a result of human activities.

Air Pollution

In the past, people assumed that the atmosphere was so vast that materials released into the air would be widely dispersed and their effects would be minimal. But today, several types of air pollution are so widespread that they damage whole ecosystems.

Acid Rain

Acid rain is created when nitrates and sulfates released into the air by the burning of fossil fuels combine with atmospheric water to form acids that fall as rain. Acid rain lowers the pH of soil moisture and water bodies. Increased acidity alone damages many plant and animal species; for instance, acid rain has been blamed for the death of large number of trees in Europe and North America. As the acidity of water bodies increases, many fish either die or fail to spawn (Figure 6). Both

Figure 6 The pH scale, indicating ranges at which acidity becomes lethal to fish. Studies indicate that fish, amphibians, and invertebrates are disappearing from heavily acidified lakes. Reproduced from Cox GW (1993) *Conservation Ecology: Biosphere and Biosurvival*. Dubuque, IA: W. C. Brown; based on data from the US Fish and Wildlife Service.

increased acidity and water pollution are two likely causes of the dramatic decline in amphibian populations throughout the world.

Ozone Depletion and Ultraviolet Radiation

As a result of human use of chlorofluorocarbons (CFCs) and other ozone-depleting chemicals, the atmospheric ozone layer has been significantly reduced. Ozone plays an important role in filtering out harmful ultraviolet radiation in sunlight. With less atmospheric ozone, more solar ultraviolet radiation reaches the Earth's surface. In humans, exposure to this UV radiation increases the risk of skin cancer. This increased UV radiation will also possibly have a significant negative impact on animals and plants exposed to direct sunlight, such as amphibian eggs on the water surface.

Ozone and Smog

Cars, power plants, and other industrial activities release hydrocarbons and nitrogen oxides as waste products. In the presence of sunlight, these chemicals react with the atmosphere to produce ozone and other secondary chemicals, collectively called photochemical smog. Although ozone in the upper atmosphere is important in filtering ultraviolet radiation, a high concentration of ozone at ground level damages plant tissues and makes them brittle, harming biological communities and reducing agricultural productivity. Ozone and smog are detrimental to both people and animals when inhaled, so controlling air pollution benefits both humans and biodiversity.

Effects on Lichens

Even when communities are not destroyed by air pollution, species composition may be altered as more susceptible species are eliminated. Lichens, symbiotic organisms composed of fungi and algae that can survive in some of the harshest natural environments, are particularly susceptible to air pollution. Because each lichen species has a distinct tolerance to air pollution, the composition of the lichen community can be used as a biological indicator of the level of air pollution.

Global Climate Change

Scientists are now intensively studying atmospheric carbon dioxide, methane, and other greenhouse gases that are

transparent to light but that absorb heat. During the past century, global levels of carbon dioxide (CO₂), methane, and other trace gases have been steadily increasing, primarily as a result of burning coal, oil, and natural gas. Clearing forests to create farmland and burning firewood for heating and cooking also contribute to the rising atmospheric concentration of CO₂, which has increased from 290 to 387 parts per million (ppm) over the last 100 years and is projected to double in the latter half of this century. Humans currently release about 70 million tons of CO₂ into the atmosphere every day.

Climate Change Predictions

Many scientists agree that these increased levels of greenhouse gases have affected the world's climate already, and that these effects will intensify in the future. The best evidence suggests that world climate has warmed by 0.6° Celsius (°C) over the last 100 years. Temperatures at high latitudes have increased even more, by 2–4 °C. Over the last 50 years, the Atlantic, Pacific, and Indian oceans have increased in temperature by 0.06 °C. Even with all of the available weather data, simulation models, and supercomputers, predicting future weather patterns is extremely complex and difficult. However, the consensus among leading scientists is that the global climate will increase in temperature by an additional 2–4 °C by 2100 as a result of increased levels of carbon dioxide and other gases in the atmosphere (Figure 7). The increase could be even greater if carbon dioxide levels rise faster than predicted, but it could also be slightly less if all countries agree to reduce emissions of greenhouse gases. The increase in temperature will be greatest at

high latitudes and over large continents. Many scientists also predict an increase in extreme weather events such as hurricanes, flooding, snowstorms, fires, and regional drought.

Extinctions and Climate Change

As a result of global climate change, climatic regions in the northern and southern temperature zones will be shifted toward the poles, forcing species to migrate. It seems likely that many species will be unable to disperse rapidly enough to keep up with the changing climate. Habitat fragmentation caused by human activities may further slow or prevent many species from migrating to new habitats or escaping rising sea levels. Many species with limited distributions and poor dispersal ability will undoubtedly go extinct, with new communities favoring widely distributed and easily dispersed species. Endemic mammals that are restricted to isolated mountain peaks or fish species found in a single lake are examples of species that will not be able to easily cross inhospitable terrain to reach a new habitat. The best hope for many species will be to migrate higher on mountain slopes or to disperse along valleys, rivers, and coastlines that are aligned north to south. Warming waters and rising sea levels are already affecting marine species as well.

Concerns about global climate change, as important as they are, should not divert our attention from the massive habitat destruction that is the principle current cause of species extinction. The preservation of intact communities and the restoration of degraded communities are the most important and immediate priorities for conservation.

Figure 7 Computer models of global climate predict that temperatures will increase significantly when CO₂ levels double in the mid- to late part of this century. Predicted temperature increases for 2080–2099 are shown, indicated as the amount of deviation (in °C) from mean surface temperatures recorded for 1980–1999. Reproduced from Primack RB (2010) *Essentials of Conservation Biology*, 5th edn. Sunderland, MA: Sinauer Associates, and Intergovernmental Panel on Climate Change (IPCC) (2007) *Climate change 2007: The physical science basis*. In: Solomon S, Qin D, Manning M, et al. (eds.) *Contribution of Working Group I to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change*. Cambridge, UK: Cambridge University Press, with permission from IPCC.

Overexploitation

Exploitation in Traditional Societies

People have always hunted and harvested the food and other resources they need in order to survive. As long as human populations were small and the methods of collection simple, harvesting and hunting were sustainable. In traditional societies, restrictions were often imposed to prevent overexploitation of natural resources. For example, the rights to specific harvesting territories were rigidly controlled; hunting in certain areas was banned; there were often prohibitions against taking females, juveniles, and undersized individuals; certain seasons of the year and times of the day were closed for harvesting; and certain efficient methods of harvesting were not allowed. These restrictions, which allowed traditional societies to exploit communal resources on a long-term, sustainable basis, are almost identical to the rigid fishing restrictions imposed on and proposed for many fisheries in industrialized nations. Among the most highly developed restrictions were those of the traditional or artisanal societies of Micronesia and Polynesia. However, there are also numerous cases of large bird and mammal species being hunted to extinction by traditional people using simple methods of hunting.

Exploitation in Modern Societies

As human populations have increased in number and size, their use of the environment has escalated, and harvesting methods have become dramatically more efficient. This has depleted large animals almost completely from many biological communities, leaving strangely empty habitats. In tropical rain forests and savannas, guns are now used instead of blowpipes, spears, or arrows. In the oceans, fish are caught by enormous factory ships and sold in the global market. Even small-scale local fishermen now have outboard motors on

their canoes and boats, allowing them to harvest from a wider area more rapidly.

In much of the world today, resources are exploited opportunistically. If a market exists for a product, local people will search their environment to find and sell it. Whether people are poor and hungry or rich and greedy, they will use whatever methods are available to secure that product. Sometimes traditional groups will sell the rights to a resource, such as a forest or mining area, for money to buy desired goods. In rural areas, traditional controls that strictly regulated the extraction of natural products have generally weakened, if not eliminated by substantial human migration, civil unrest, or war. As a result, species are more easily exploited to the point of extinction.

Trade in Wildlife

The legal and illegal wildlife trade is responsible for the decline of many species. Worldwide trade in wildlife is valued at over \$10 billion per year, not including edible fish. The fur trade has reduced the chinchilla (*Chinchilla* spp.), vicuña (*Vicugna vicugna*), giant otter (*Pteronura brasiliensis*), and numerous cat species to low numbers. Overharvesting of butterflies by insect collectors; of orchids, cacti, and other plants by horticulturists; of marine mollusks by shell collectors; and of tropical fish for aquarium hobbyists are other examples of targeting whole biological communities to supply an enormous international demand (Table 1). For instance, it has been estimated that 350 million tropical fish valued \$1 billion are sold worldwide for the aquarium market, and many times that number are killed during collection and shipping.

Besides a surprisingly large legal trade, billions of dollars are involved in the illegal trade of wildlife. A black market links poor local people, smugglers, corrupt customs officials, rogue dealers, and wealthy buyers who do not question the sources they buy from. This trade has many of the same

Table 1 Major groups targeted in the Global Wildlife Trade

Group	Number traded annually ^a	Comments
Primates	40,000	Mostly used for biomedical research; also for pets, zoos, circuses, and private collections.
Birds	4 million	Zoos and pets. Mostly perching birds, but also legal and illegal trade of about 80,000 parrots.
Reptiles	640,000	Zoos and pets; also 10–15 million raw skins. Reptile extracts are used in some 50 million manufactured products (mainly from the wild, but increasingly from farms).
Ornamental fishes	350 million	Most saltwater tropical fish come from the wild, caught using illegal methods that damage other wildlife and the surrounding coral reefs.
Reef corals	1000–2000 tons	Reefs are being destructively mined to provide aquarium decor and coral jewelry.
Orchids	9–10 million	Approximately 10% of internationally traded orchids are from the wild. These are sometimes deliberately mislabeled to avoid regulations.
Cacti	7–8 million	Approximately 15% of the traded cacti come from the wild, with smuggling a major problem.

^aNumbers refer to the number of individuals unless otherwise specified.

characteristics and practices, and sometimes the same criminal players, as the illegal trade in drugs and weapons. Confronting these illegal activities has become a dangerous job for international law enforcement agencies. Clearly, people involved in the illegal trade of wildlife are not concerned about species going extinct, unless it affects their profits.

Overfishing

In the North Atlantic, one species after another has been overfished to the point of diminishing returns. The Atlantic bluefin tuna, for example, has experienced a 97% population decline since 1960. Similar grim scenarios can be recounted for other prized large fish, such as the swordfish (*Xiphias gladius*). One of the most dramatic cases of overexploitation in recent years is related to the booming demand for shark meat and shark fins, caused in large part by the popularity of shark fin soup in Asian restaurants. Shark fishing has become a lucrative alternative to targeting severely depleted commercial fish populations. But many shark populations are now declining dramatically as well, because most species have a relatively slow reproductive cycle. Heavily fished shark populations in the Atlantic, for instance, have declined by 40–99% over the last 20 years, and some species there and elsewhere may soon go extinct.

Another striking example is the enormous increase in demand for seahorses (*Hippocampus* spp.) in China, which is tied to the nation's economic development. The Chinese use dried seahorses in their traditional medicine because it resembles a dragon and is believed to have a variety of healing powers. Approximately 45 t of seahorses are consumed in China per year – roughly 16 million animals. Seahorse populations throughout the world are being decimated to supply this ever-increasing demand, and international trade is now carefully regulated.

Exotic Species

Humans have radically altered the patterns of species distributions by deliberately or accidentally transporting species throughout the world. The extent of this modern movement of human-transported species is unprecedented and has been described by Elton (1958) as “one of the great historical convulsions of the world's flora and fauna.” Many areas of the world are strongly affected by exotic species. For instance, the US currently has over 20 species of exotic mammals, 53 species of exotic reptiles and amphibians, 88 species of exotic molluscs, 97 species of exotic birds, 138 species of exotic fish, 4500 species of exotic insects and other arthropods, and 5000 species of exotic plants.

The great majority of exotic species do not become established or dominant because the new environment is not suitable. However, some species do establish themselves in their new homes, and many of these become abundant at the expense of native species. Exotic plants frequently displace native species because they are better suited to the new conditions created by people, such as increased fire and introduced grazing animals. Exotic perennials completely dominate many North American wetlands: purple loosestrife (*Lythrum salicaria*) from Europe overgrows marshes in eastern North

America, whereas Japanese honeysuckle (*Lonicera japonica*) forms dense tangles in bottomlands of the southeastern US.

Exotic species are also often able to thrive because their populations are not held in check by any of the local parasites or predators. These exotic species may displace native species through competition for limited resources, they may kill and eat native species to the point of extinction, or may alter the habitat so that many natives are no longer able to persist. The effects of exotic insects on the native insect fauna can be devastating. At some localities in the southern US, insect species diversity has declined by 40% following the invasion of exotic fire ants, which attack, consume, or outcompete other insect species. Many bird species have dramatically declined after fire ants entered their habitat, because of direct attack or loss of insect prey.

Exotic species are considered the most serious threat facing the biota of the national park system in the US. The effects of habitat degradation, fragmentation, and pollution can potentially be corrected and reversed in a matter of years or decades as long as the original species are present. It may be expensive, difficult, or even impossible, however, to eliminate exotic species that have become abundant, widely dispersed, or thoroughly integrated in the community.

Exotic Species on Islands

Because they have evolved in the absence of mainland herbivores and predators, island species are particularly vulnerable to exotic species; the introduction of one exotic species to an island may cause local extinction of numerous native species.

On Santa Catalina Island off the coast of California, 48 native plant species have been eliminated, primarily due to grazing by introduced goats, pigs, and deer. One-third of the plant species currently found on the island are exotics. Several native plant species have reappeared after goats were removed from part of the island.

Birds of the Pacific are also vulnerable to exotic species. The brown tree snake (*Boiga irregularis*; **Figure 8**) has been introduced onto a number of Pacific islands, where it is devastating endemic bird populations by eating eggs, nestlings, and

Figure 8 The brown tree snake (*Boiga irregularis*) has been introduced onto many Pacific islands, where it devastates populations of endemic birds. This adult snake has just swallowed a bird. (Photograph by Julie Savidge).

adults. On Guam alone, the brown tree snake has driven 10 of 13 endemic bird species extinct. Recent visitors have remarked on the absence of birdsong: "Between the silence and the cobwebs, the rain forests of Guam have taken on the aura of a tomb" (Jaffe, 1994).

Exotic Species in Aquatic Habitats

Exotic species can have severe negative effects on vulnerable freshwater communities, particularly lakes and isolated stream systems. Shipping is a major cause of introductions, moving species that are attached to ship hulls or contained in ballast water. There is also a long history of introductions, many accidental, of exotic commercial and sport fish species into lakes. These exotic fish, often larger and more aggressive than the native fish fauna, may eventually drive the local fish species to extinction. Aquatic plants, invertebrates, and disease organisms can also become aggressive exotics outside their normal range.

One of the most alarming recent invasions in North America was arrival of the Eurasian zebra mussel (*Dreissena polymorpha*) in the Great Lakes in 1988. Within two years, zebra mussels had reached densities of 700,000 individuals per square meter in parts of Lake Erie, choking out native mussel species. They have subsequently been found in the Detroit, Cumberland, and Tennessee Rivers. As it spreads south, this exotic species is causing enormous economic damage to fisheries, dams, power plants, water treatment facilities, and boats, as well as devastating the aquatic communities it encounters.

Invasions also occur in marine and estuarine systems, with 84% of marine areas worldwide affected by at least one invasive species. In the Mediterranean, the invasive green alga *Caulerpa taxifolia* is outcompeting native algae species and reducing fish abundance. Because *Caulerpa* is used as a decorative plant in marine aquariums, this is an example of one negative human impact (the trade in aquarium and ornamental species) resulting in another. One solution would be to ban harmful invasive species from the aquarium trade and provide a list of noninvasive alternatives.

Disease

Disease caused by internal parasites is a natural control mechanism that reduces populations when they reach high densities. However, levels of disease can often increase in populations as a result of human activity. When animals are confined to habitat fragments at abnormally high densities, disease may spread more easily among individuals. Also, animals that are stressed or weakened by living in a degraded or polluted environment may be more susceptible to disease. Furthermore, as habitats are fragmented by human activities, disease can spread more easily from domestic animals into wild populations. At Tanzania's Serengeti National Park, at least 25% of the lions (*Panthera leo*) have recently been killed by canine distemper, a viral disease apparently contracted from one or more of the 30,000 domestic dogs living near the park. For endangered species, such outbreaks can do phenomenal harm: The last population of black-footed ferrets

Figure 9 Populations of flowering dogwood (*Cornus florida*) are declining in eastern North American forests due to anthracnose disease, which is caused by the introduced fungus *Discula destructiva*. (Photograph by Jonathan P. Evans).

(*Mustela nigripes*) known to occur in the wild was destroyed by canine distemper virus. Ironically, some conservation efforts may also increase susceptibility to disease; for instance, species in captive breeding programs may contract diseases from other animals or even humans.

Diseases transported by people to new parts of the world can also decimate species. North American chestnut trees (*Castanea dentata*), once common throughout the eastern US, have been virtually obliterated by an ascomycete fungi carried on Chinese chestnut trees imported to New York City. Introduced fungal diseases are also eliminating elm trees (*Ulmus americana*) and flowering dogwoods (*Cornus florida*) from North American forests (Figure 9). Introduced diseases have particularly powerful adverse effects on endemic island species. Many endemic Hawaiian bird populations have been decimated and even driven to extinction by introduced avian malaria protozoans spreading from introduced bird species through introduced mosquitoes.

Increased rates of disease in animal populations can also negatively impact humans. The risk of diseases such as West Nile virus, Lyme disease, and bird flu being transmitted from animals to humans is increasing with increased movements of humans and domestic and wild animals around the world, as well as with warming temperatures that may be allowing disease-causing organisms to expand their ranges.

Multiple Factors

A combination of factors acting simultaneously or sequentially can overwhelm a species, as illustrated by the case of the large freshwater mussel *Margaritifera auricularia*. This species was formerly known from Western Europe to Morocco, but now it occurs in only one river and its adjoining canals in Catalonia, Spain. Humans have used its attractive shell and pearls as ornaments since the Neolithic Age. The main reason for its decline, overharvesting, originally led to its disappearance from rivers in Central Europe in the fifteenth and sixteenth centuries. In more recent times, pollution, destruction of freshwater habitats, and overharvesting continue to reduce

its range. The mussel is also affected by the loss of other species, because its larval stage needs to attach to certain species of fish to complete its life cycle. Unless strict conservation measures are implemented to prevent overharvesting, control water quality, maintain fish stocks, and protect mussel habitat, this culturally important species will soon be extinct. Such comprehensive conservation strategies are often needed to deal with the multiple threats to species.

Threats to biological diversity come from a number of different directions, but their underlying cause is the same: the magnitude of destructive human activity. It is often easy to blame a group of poor, rural people, or a certain industry for the destruction of biological diversity, but the real challenge is to understand the local, national, and international linkages that promote the destruction and to find viable alternatives. These alternatives must include stabilizing the size of the human population, finding livelihoods for rural people that do not damage the environment, providing incentives and penalties that will convince industries to value the environment, and restricting trade in products that are obtained by damaging the environment. Yet an equally important part of the solution is to increase the willingness of wealthy and middle-class people in both developed and less-developed countries to reduce their consumption of the world's resources and to pay fair prices for products that are produced in a sustainable, nondestructive manner.

Glossary

Background extinction A distinctly lower rate of extinction, more typical of most of the fossil records.

Extinction rate Number or proportion of taxa becoming extinct per unit time or after an important geological temporal boundary.

Mass extinction Extinction occurring over a short period of time that is of large magnitude, wide biogeographic impact, and involves the extinction of many taxonomically and ecologically distant groups.

Introduction

Why the Fossil Record?

Many species are threatened by impending extinction and attempts have been made to assess population declines and to enact policies of recognizing endangerment by rules, such as the International Conservation Union's rule of three successive years of 80 percent decline. It is difficult to develop a measure of extinction rates of entire flora or fauna, only because we usually have scant knowledge of the species pool before the impact. This is particularly a problem in species-rich tropical habitats, where cryptic species abound, yet have not been identified completely. Surveys of specially rich fauna in tropical wet forests are only being organized now, and the decline of the areal extent of these forests in recent years makes it nearly impossible to measure extinction rates, except by means of indirect estimates of species-area relationships. The same applies to species-rich marine communities such as coral reefs.

Extinction is very much the domain of a paleontologist. It is believed that we are now possibly living through a mass extinction caused by human disturbance of high diversity tropical habitats. But very little is known about the extinction of species, except by fairly obvious mechanisms such as hunting. Can knowing that the Dodo or the Passenger Pigeon was hunted to extinction help very much with understanding climatically induced changes in key structural groups such as forest trees and reef corals, and their dependent species? Could such spotty knowledge be used to extrapolate to the broad sweep of geological time? Paleontological data has the advantage of large banks of "before and after" data on biodiversity on time scales that can be related to global climate change. Its weakness, however, is in associating extinctions with unique causes, as shall be seen.

Invasions have caused extensive extinctions on oceanic islands, particularly when alien predators overwhelmed small populations of endemic species in a matter of decades. Extinction on larger time scales, even over hundreds of years, is much more difficult to track. Unfortunately, the time scale for larger-scale changes over 100,000 years or more is probably unapproachable by the neontologists, who can only observe "normal" extinction, and don't have much understanding of what occurs normally. It may be that fine-scale studies of the fossil record may eventually give us more insight into

species-level extinction than neontological studies ever will. After all, the durations of animal species life spans range from the order of 10^5 (land vertebrates) to 10^6 – 10^7 years (marine species). Even with millions of living species, we are not likely to be able to document many cases of typical extinction of living animal species. The fossil record is probably our only hope of a model for study of extinction rates, especially on the scale of ocean basins and continents.

Although its coverage of the total potential living biota is incomplete, the fossil record affords us a more complete glimpse of extinction rates of a number of readily fossilizable groups, both marine and terrestrial. We have a reasonably complete database that has stabilized over the years and one can readily trace extinctions across geological time horizons. A great advance is the Paleobiology Data Base (<http://paleodb.org>), which records as of the year 2011 nearly a million fossil occurrences with a wide variety of synthesis of data. The fossil record moreover gives us a deeper insight into what extinction really means. After all, we would like to produce a prospectus of the biological future of living communities following an extinction. Does the loss of a species have a disproportional importance, resulting in the extinction of many associated species? Following an extinction event, is there enough redundancy that allows the surviving species to evolve a new diverse fauna? Does the extinction of certain species cause the snowballing of a larger extinction event? With some judicious reasoning we can infer the answers to some of these questions with the use of the fossil record.

Measures and Types of Extinction Rates

Many extinctions in the fossil record appear to be precipitous, and occur over short time period of hundreds of thousands to a few million years. Impacts of extraterrestrial objects may have caused changes in a year or less. Such length of time is short when you consider the length of the record of the Phanerozoic Era (542 My).

It is possible to quantify the extent of the extinction with the following data:

1. The total pool of taxa before the extinction;
2. the number of taxa that became extinct;
3. the time span over which the extinction occurs.

We could calculate the number of taxa that become extinct or the percent of the former pool of taxa that became extinct. Time could be measured in years, but often we only have segments of relative geological time units such as geological stages. (A set of stages comprises a geological series, and a set of series comprises a geological period (e.g., Cambrian, Cretaceous).) In many parts of the fossil record, the absolute time represented by a stage is not accurately known, and different geological stages are often of great difference in temporal extent.

Charles Lyell developed an ingenious technique to estimate extinction rate by charting the gradual diminution of living species as one went back in geological time. This type of analysis can give longevities and extinction rates. Such Lyellian curves demonstrate, for example, that the diminution of bivalve species on the Pacific coast of the USA is at a steady pace whereas a more precipitous extinction occurred in the Atlantic.

Problems in Measuring Extinction Rates

Taxon-Level Bias

We typically think of extinction rate as a measure of the loss of species. To create a database for paleontology, the species level is very difficult to trust with any degree of confidence; most paleontologists tend to trust the genus and higher taxonomic levels in identifications. In recent years, more and more effort has been directed toward accounting for the ranges of all named species in the fossil record, but most analyses have been done at the family or genus level. The large-scale database we now employ owes its existence to the dedicated work of David Raup and especially the late Jack Sepkoski, who continuously sought to produce a more complete database of the geological ranges of all fossil groups. Initially, the compilation was at the level of taxonomic order but subsequent analyses have moved down the taxonomic hierarchy to the family and generic levels.

Can extinctions of higher-level taxa be used to estimate species-level extinctions? To estimate species richness using numbers of higher-level taxa (e.g., orders), we assume that taxonomic diversity at higher taxonomic levels is correlated with species richness, but they are not necessarily correlated in this manner. This can be seen clearly where changes in ratios of one taxonomic level to another occur over broad spans of time. If the ratios change, then higher taxonomic units might be flawed estimators of changes in species diversity. For example, the ratio of taxonomic orders to families decreased significantly from the Paleozoic to the Mesozoic Era.

Over short periods of time, the number of taxa at a higher taxonomic level (e.g., level of family) might have a regular relationship with a lower taxonomic level, such as species. To estimate species-level extinction from family-level extinction, David M. Raup used a rarefaction technique based on the sampling curve that relates the number of species collected at random to the number of families recovered. This method has been modified and refined to be used in many estimates of standing fossil diversity.

The rarefaction approach is the best we have so far. Nevertheless, we must be careful in applying it. The biggest problem is the potential change in the relationship over

geological time. For example, the ratio of families to species decreases by a factor of two from the Mesozoic to the Cenozoic, and other cases are known of changing ratios of species to genera. Selective extinction can also bias our conclusions. For example, certain families may be much more prone to extinction, due to their presence in a particularly vulnerable habitat (e.g., coral reefs during a cooling event). This might overestimate total extinction, if these are added to a larger species list. It is also difficult to get sufficient data to calculate good rarefaction curves for all but the most abundant fossil groups.

Raw Data for Analyses

Any set of diversity data involves a count of the number of taxa. But this number is strongly modulated by the intensity of sampling. Thus diversity could be inflated simply because more studies have been done in a given locality at a given time interval. Thus raw data must be corrected for sampling intensity. In most instances, the genus is the level used for diversity estimates, so the number of genera must be estimated by some sort of sampling process that corrects for the total number of studies, the number of localities, and the number of fossils that are collected at any one locality and time horizon. Two examples of these potential biases are the possible monograph effect of studying intensively one part of geological time and a bias that inflates the diversity of parts of the geological record just before the present, because species are still alive and can be sampled and studied more completely than their antecedents.

Biased Preservation and Convergence

Estimates of extinction rates may be biased by preservation and abundance at the time of extinction. Preservation of appropriate habitats during an extinction may be greatly reduced. Thus a species might have survived, but there are no opportunities to see it because its usual facies of occurrence has not been preserved.

A common change in probability of preservation occurs when a systematic change in rock preservation occurs, as in the reduction of deposition during a regression phase of the sea, as at the end of the Permian and just before the end of the Cretaceous (regression refers to a lowering of sea level in a given area; transgression refers to a rise in sea level). Suppose the ranges of a group of species all ended at the very terminus of the Cretaceous. A gradual reduction of deposition would, by sampling error alone, give the impression of a gradual disappearance of the fossil species. Even if deposition does not decline, previously rarer species would be difficult to sample for presence during a general decline in abundance during extinction, just because we would be unlikely to find them. These biases have come to be known as the Signor-Lipps effect, or "backward smearing," because a sharp extinction might appear to be gradual from fossil sampling. Only abundant forms would be sufficiently "findable" that we could assess their total geological range with confidence, especially up to the time of their extinction. Even at smaller levels of geological resolution, the problem of a spurious component of estimated diversity due to the preservation of different amounts of rock of a given age is a major source of bias. The problem is compounded by cases where some environmental factors

simultaneously affect both the amount of sediment accumulation for a given time period and biodiversity.

Accurate Estimate of Fossil Ranges

To estimate extinction rates one must have an accurate accounting of the geological ranges of species. Then at any time horizon one would be able to account for the number of taxa that disappear from below to above the horizon.

Preservation and rock distributions may strongly bias our perception of geological ranges of taxa. All geological ranges of fossil groups are incomplete, due to lack of appropriately preserved habitats and poor preservation. As incompleteness, or gaps, between fossil occurrences in a vertical section increases, it stands to reason that the actual temporal range of a taxon is greater than what the record would indicate. The number of gaps in preservation may also be combined with a fossil recovery potential curve, which might correct for a change in the probability of preservation during the history of the taxa in question. On the grand scale, the volume of rock correlates positively with the total number of fossil taxa recovered in both marine and terrestrial environments; this suggests that incompleteness of preservation of environments may give us a false impression of true diversity. Although methods have been developed to relate the degree of incomplete preservation to true geological range, the estimated error may sometimes make it very difficult to determine whether, for example, many species became extinct in the same short time period. Some proportion will appear to have disappeared earlier due to incomplete preservation.

Extinction Must be Compared with Origination Rates

If extinction occurs over a very short period of time, one can count the number of species before and after an event and assume that the decline can be explained by extinction alone. But speciation may be occurring continuously, which means that a decline in species richness may just as easily stem from a drop in speciation rate as an increase in extinction. Alternatively, speciation might keep pace with extinction, resulting in no loss of biodiversity. When the speciation and extinction rates are equal, an equilibrium exists, meaning the number of taxa remains constant. At the end of the Devonian, for example, large speciation rates balanced high extinction rates. But speciation rates collapsed during the latest Frasnian (Upper Devonian), which precipitated a severe reduction of marine species diversity. A dramatic extinction of mollusk species occurred in the subtropics of the western north Atlantic at the end of the Pliocene (*ca.* 3 million years ago) but this loss was more than compensated by the origin of new species. Problems also arise when species appear and disappear during an interval. Counts before and after this interval will therefore ignore a significant fraction of the appearances and extinctions.

Pseudoextinction

In many cases, paleontologists have followed lineages through a geological column and have named successions of species, which are recognized by a variety of character transformations. Thus, even though a lineage may not become extinct, the morphological changes result in an arbitrary extinction or pseudoextinction. Pseudoextinctions are a significant fraction

of the total disappearances of taxonomic names from one geological horizon to the next.

Phylogenetic Approaches

We are mainly considering taxic approaches to extinction, where the number of taxa appearing and becoming extinct are to be estimated. But much can be learned when considering the evolutionary position of taxa on a tree of evolutionary relationships. If we had a complete evolutionary tree, complete with living species and all preserved species that became extinct, we could estimate the extinction rate as the number of species that became extinct divided by the total of the branch lengths of the phylogeny. Because most fossil groups are incompletely sampled, it is usually not possible to take such a simple approach. Instead, models incorporating estimates of appearance and extinction rates in relation to tree structure and independent estimate of clade age (e.g., molecular clock estimates) can be used to estimate the extinction rate.

Other Biases

Paleontologists are accustomed to dealing with a wide range of problems in preservation. Occasionally, an exquisitely preserved fossil biota, such as the Middle Cambrian Burgess Shale, demonstrates that most of the remaining fossil records have not preserved a wide variety of soft-bodied species and even a number of skeletonized taxa. Such unevenness of preservation also works at smaller scales and therefore preservation strongly biases our estimates of diversity. Monographic studies of the fossil record are also uneven and descriptions of species are often strongly correlated with the intensity of study by specialists, either between fossil groups or between time horizons. Recent studies have attempted to correct these problems by normalizing diversity estimates by the number of monographs produced for a given group at a given time.

Mass Extinction

Definitions and Identification of Mass Extinction

Although diversity in the fossil record was first characterized in 1860 by John Phillips, strong temporal changes in taxon turnover were quantified first in the 20th century by paleontologist Norman Newell, who found peaks of activity in the Ordovician, Carboniferous, and Jurassic. Declines in standing taxon richness were simultaneous and relatively rapid among distantly related taxa, although increases were not so obviously coordinated. We can see in [Figure 1](#) five conspicuous and precipitous drops in diversity, the most dramatic occurring at the end of the Permian. David M. Raup and John J. Sepkoski Jr analyzed the overall extinction rate of marine taxa at the family level and found that four events fell outside of a one-sided 99 percent confidence interval from the mean extinction rate trend: Ashgilleen (Upper Ordovician); Frasnian (Late Devonian); Guadalupe-Dzhulfian (Late Permian); and Maastrichtian (Late Cretaceous). The Norian (Upper Triassic) fails this test but its wide-spread occurrence forces us to include it in the "big five" ([Table 1](#)). A recent compilation of stratigraphic ranges over a wide variety of taxa produced by a wide variety of specialists. Inspection of extinction rates revealed peaks at the

Table 1 Percent extinction ((extinctions/standing taxon richness) $\times$ 100) at the five major mass extinctions in the fossil record (after Jablonski 1994)

Mass extinction	Families		Genera	
	Observed extinction	Calculated species-level extinction	Observed extinction	Calculated species-level extinction
End-Ordovician 439 Ma	26	84	60	85
Late Devonian 367 Ma	22	79	57	83
End-Permian 243 Ma	51	95	82	95
End-Triassic (Norian) 208 Ma	22	79	53	80
End-Cretaceous 65 Ma	16	70	47	76

same times identified by Sepkoski, and, indeed, by paleontologists traditionally.

The big drops, mass extinctions, have been distinguished from background extinction, which refers to the remainder and overwhelming majority of extinctions. Although the big five are conspicuous, other mass extinctions have been recognized. About half of the marine genera disappeared in the Lower Cambrian and archaeocyathid reefs were decimated, perhaps due to wide-spread marine anoxia. Another possible anoxic event caused a major extinction at the Cenomanian–Turonian boundary (Upper Cretaceous), although lowered productivity and global cooling may have contributed. John Alroy's analysis of the Phanerozoic fossil record suggests that perhaps one cannot justify a distinct class of mass extinctions by means of numerical changes alone.

Statistical tests of mass extinction do not inspire confidence, because they combine many taxonomic groups of complicated taxonomic structure, reify them to independent data points, and usually analyze them using the assumptions of parametric statistics. Because the groups are enmeshed in a phylogenetic tree structure, it is not easy to perform such analyses and distributions of extinction events are usually skewed toward many events of extinction rates of a few percent. There may be as many as 12 mass extinctions.

It may seem inappropriate to fix on mass extinctions, which could be atypical end members, but if we cannot characterize these events, will we be able to explain the smaller extinctions that were far more common in the history of life? If mass extinctions are more or less larger scale or even global versions of what might happen on a more local scale (extinctions stemming from, for example, local tectonism, anoxia, regional sea-level change) then maybe we can extrapolate what we learn about them to smaller scales, and *vice versa*. If we focus on times of heightened turnover in taxon richness that are confined to basins, we might see mass extinctions writ small. There is some reason, however, to believe that the “big five” were distinctive and the effects of extinctions during these times transcended those of more mundane times.

If an extinction event is a statistical outlier, then how could we justify a separate category, and would this category require a set of extinction mechanisms that differ qualitatively from background extinction? This question opens up a can of worms. There has been a good deal of debate about what a statistical outlier really is and whether mass extinctions are really different from lesser periods of extinction. If we assembled extinction rates into a frequency distribution curve, we might argue that the mass extinctions sit squarely on the tails of some expected probability distribution, or a kill curve.

The distribution of the risk of marine genera consists of groups with mainly low risk and some of much higher risk. With no mechanistic model in mind, it is not clear whether the somewhat bumpy distribution of extinction rates of marine genera is smooth or discontinuous, and we have no idea of the distribution for species. If we have to wait 100 My for a mass extinction, are we waiting for an intense version of the same stuff or a truly distinctive event?

In the context of the time that they occur, mass extinctions are clear and major drops in taxon richness, distinct from extinction rates in the time periods before and after. The Permian appears as a sharp trough after an Early Paleozoic time of expansion and then stabilization of numbers of taxa. The same can be said for the End-Cretaceous extinction. But numbers really tell only part of the story. A criterion based on a high extinction rate alone would stretch the confidence we have in our statistical assessments too far, and should only be a means of screening for candidates. To qualify, mass extinction events must have the following features:

1. The number of taxa becoming extinct is significantly greater than times of other extinctions.
2. The decline is concentrated in a small fraction of the Phanerozoic, for example, less than a geological series, or at most a few million years.
3. The extinction is broad-based taxonomically, affecting many distantly related taxa that have not arisen in the same time period as the decline.
4. The extinction affects many different biomes, perhaps not equally. For example, a mass extinction would not be confined to epibenthos on hard surfaces of a region, as opposed to coeval soft-bottom benthos living in the same area.
5. The extinction is geographically widespread, most likely global, in extent.
6. Mass extinction may be caused by mechanisms qualitatively different from background extinctions, but it may be caused merely by “much more of the same” (e.g., anoxia, climate change, unusually large extraterrestrial impacts).
7. Mass extinction affects taxa differently than during other extinctions; small-scale influences on the degree of extinction, such as geographic range are swamped during mass extinctions. David Jablonski found that during ordinary extinctions, species with greater geographic ranges were less prone to become extinct.
8. The recovery period following the mass extinction marks the rise of either new taxonomic groups, the expansion of formerly rare groups, or complete reorganization of ecosystem structure.

Table 1 demonstrates two important issues in quantifying the degree of extinction. First, the extinction event is characterized as a loss. But the nature of loss is unclear, as it may result from declining speciation rates, increasing extinction rates, or both. Secondly, in the case of mass extinctions, speciation usually declines and extinction rate increases precipitously. **Table 1** shows the startling results: About 95 percent of the marine (readily fossilizable) species became extinct at the end of the Permian, and the others of the “big five” took similarly big hits. The Permian was also bad for taxonomic families (*ca.* 50 percent loss), but the others hovered around 20 percent. The lower loss of families in many extinctions suggests that there might be survivors of many families that could recover and proliferate new species following the extinction.

A compilation of major changes in both terrestrial and marine fossil groups, coordinated by Michael Benton, reveals some important features of the fossil record. For instance, extinction rate can be very high, with not much overall effect on total diversity, because originations may be high or even higher. Thus if one considers extinction rate separately, the Cambrian must be added to our roster of mass extinctions. In terms of percentage extinction, it looms over the rest of the fossil record, even the Permian. There is a possibility, however, that this extinction is more apparent than real. Some have argued that poor Upper Cambrian preservation biases our perception of Cambrian diversity. The analysis reveals a number of extinction peaks not easily seen in a plot of diversity alone. Most notable are strong extinctions in the Carboniferous, Jurassic, and Mid-Cretaceous periods.

The quantitative aspects of mass extinction should not obscure some of the major qualitative effects, causing irreversible changes in the world's biota and therefore major reorganization of the structure of life. At the end of the Permian, marine communities were reorganized completely due to the end of dominance by brachiopods and the extinction of long-abundant forms such as trilobites. In most parts of the world, the end of the Permian was also the end of a sea bed dominated by relatively sluggish and often sessile passive suspension-feeding groups, leading to replacement by sea-bed communities with more active roving individuals. The end of the Mesozoic witnessed the demise of the long-abundant carnivorous ammonites, leaving the modern world with a pitiful representation of the former glory of externally-shelled cephalopods. Bivalves such as the inoceramids and rudists dominated Cretaceous shallow-water seas but they disappeared. Of course, the dinosaurs also became extinct at this time, which presaged the evolution and diversification of the modern orders of mammals.

It is often difficult to estimate the time span over which extinction occurred, due to strong uncertainty in the time span of geological stages, which is often the crucial level at which extinction is assessed. This is particularly a problem in the early and middle part of the Paleozoic, where time estimates of stage lengths are difficult to estimate with certainty. Within stages, rates are especially difficult because of uneven rates of sedimentation, which makes it invalid to assume a linear relationship between meters of geological section and time. For example, during the final flood stage of transgression of the sea, sedimentation rates are often very low, and much time may be compressed in very little geological section.

The estimate of extinction is plagued by other factors as well. Worst of all, the incompleteness of the fossil record imposes biases that cloud an assessment of the tempo and degree of a mass extinction. During the Permian, an enormous regression of the sea resulted in the deposition of few marine deposits and correspondingly few marine fossils. As a result, a number of taxa appeared to become extinct, but they reappeared in the Triassic, much as Lazarus was raised from the dead. Lazarus taxa may be explained by poor preservation in all facies, resulting in poor sampling of species, even those that really existed during the low point at the end of the extinction. Even if appropriate sedimentary rocks are widespread, reductions in population size may make any species more resistant to successful sampling. Alternatively, there may be localized havens in which such taxa may survive, but these refuge environments might escape preservation. In any case, extinction is overestimated. The problem is compounded by so-called Elvis species, which evolved after a mass extinction and converge by means of natural selection to resemble pre-mass extinction morphotypes, much as Elvis impersonators now clutter the landscape, at least if you frequent Las Vegas. In Triassic reefs, sponges may be mistaken for Permian taxa, but they are unrelated.

Preservation and rock distributions may strongly bias our perception of geological ranges of taxa. A common change in probability of preservation occurs when a systematic change in rock preservation occurs, as in the reduction of deposition during a regression phase, as at the end of the Permian and just before the end of the Cretaceous. Suppose the ranges of a group of species all ended at the very terminus of the Cretaceous, a gradual reduction of deposition would, by sampling error alone, give the impression of a gradual disappearance of rarer fossil species. Thus a sudden ending of many taxa can be made to appear gradual merely by a gradual reduction of percent preservation.

Patterns of taxon survivorship of mollusks indicate that mass extinction may or may not be a qualitatively different phenomenon from background extinction. David Jablonski found that during normal periods in the Cretaceous period, extinctions of mollusks were correlated with planktotrophic larval development and geographic range; as might be expected, species with longer dispersal abilities and greater geographic range had greater survival potential. Clade survivorship was positively correlated with species richness. During the End-Cretaceous event, however, none of these generalizations were held, and clade survival was correlated only with the geographic extent of the clade. After the event, the correlations found previously were again obtained. In the End-Cretaceous extinction of planktonic diatoms, however, a different pattern emerged, as diatom species with benthic resting stages survived far better than those with no resting stages. Foraminifera species with specialized morphologies and larger sizes were eliminated and simpler morphologies were favored. Sea urchins suffered extensive extinctions across the K-T boundary, but bulk sediment processors and shallow-water herbivorous species suffered more extinction than omnivores or selective deposit feeders, which suggests a relationship between high extinction and starvation. Here, properties that normally would be related to survival of individuals can be extrapolated to taxon survival. During the Permian mass

extinction, gastropod success did not differ especially from periods of more subdued extinction, but groups with planktotrophic larvae and geographically restricted groups suffered more than average (Erwin, 1993). Thus, as extinction intensity increases, some qualitative changes may emerge for some taxa and biogeographic/dispersal properties, but not for all.

Causes of Mass Extinctions

Mass extinctions are associated in time with major environmental changes. The problem, of course, is that other times of no mass extinction also mark the times of environmental change, and it is fair to say that we could not easily predict all mass extinctions with nonfossil data alone. If environmental forcing, which transcends the abilities of species to survive or adapt, is a major cause of mass extinction, what are the factors? We can list them but finding smoking guns is often another matter.

1. Impact or a series of impacts of extraterrestrially derived objects.
2. Volcanism.
3. Climate change.
4. Lowering of sea level, which reduces available habitats for marine species.
5. Anoxia, especially transgressive spread of deep-anoxic waters onto the continental shelves.
6. Methane hydrate release, resulting in extreme global warming.

These causes, stem more from associations in time between inferred geological events and extinctions, and not from a solid model linking environmental change to extinction. The best example of the latter is the Permian mass extinction. The vast marine regression may have been the driving force behind a variety of environmental changes, including a rise in carbon dioxide, which led to increased temperature and oceanic anoxia. At the end of the Permian, sea level dropped, perhaps about 200 m, which was followed by a transgressive rise of sea level in the Lower Triassic of similar magnitude in just 2 My. Seasonality and reduction of habitat complexity during the regression may also have begotten environmental instability, beyond the adaptive ranges of a number of specialized groups. Robert Berner produced a solid model that demonstrated a remarkable drop in atmospheric oxygen from the end of the Permian to the beginning of the Triassic. The drop may have been stimulated by a period of extensive volcanism, which in turn caused dry climates and the wide-spread drying of the planet, which reduced burial of carbon in swamps and released carbon dioxide to the atmosphere. This might have caused extensive warming and temperature stress. The reduction of oxygen might have been the trigger for extinction both on land and sea. If oxygen in the ocean declined, hydrogen sulfide might have appeared, which would be poisonous to most marine life. Volcanism might be a minor contribution to climate change at the end of the Permian, because calculations preclude much of a change in the large ^{13}C deviations at this time, due to outgassing. However, the extensive volcanism in Siberia might have risen to the surface and heated up carbonates and coal deposits, liberating lethal

methane, which might have triggered extinctions and caused larger ^{13}C deviations. The Siberian traps cover an enormous area of about two million square kilometers. Paleontologists Norman Newell and Anthony Hallam have implicated sea-level change in a number of extinctions throughout the Mesozoic, but they are also often combined with other events, such as bolide impacts, anoxia, and temperature change. Douglas Erwin likened this multicomponent explanation to Murder in the Orient Express by Agatha Christie, where twelve culprits were ultimately found to have conspired to murder the victim. Great for murder mysteries but maddening for science. Even this cast of characters ignores the hypothesis of global cooling triggered by glaciation, but this may be discounted as the glacial evidence can be dated much before the extinction begins.

The Pace of Mass Extinctions

The end of the Cretaceous is not the most dramatic mass extinction in the Phanerozoic (Figures 1 and 2). At the time, however, both major terrestrial and marine elements were lost, the fauna was sufficiently modern to be understood ecologically, and some of our favorites, such as dinosaurs and ammonites bit the dust. Luis, Walter Alvarez, and colleagues set off a debate that has yet to flag by suggesting that a massive asteroid impact caused the extinctions by blanketing the earth with dust spread along ballistic trajectories outside the atmosphere. Such catastrophes had been suggested before by paleontologists, but here was the first tangible evidence.

The fact of an End-Cretaceous impact is supported by a world-wide anomaly of high concentrations of the element iridium in rocks just at the End-Cretaceous boundary (K-T boundary). Although there still is some controversy about this, extraordinarily high iridium concentrations indicate an extraterrestrial origin for some of the materials in the rock. Shock structures on quartz crystals suggest that an enormous crater should be present on a continent. A possible piece of ejecta has been found in a core of the Pacific at the K-T boundary, which indicates that the bolide was likely a typical metal- and sulphide-rich carbonaceous chondrite rather than derived from cometary materials.

The site of impact has probably been located in the megacrater at Chixulub in the Yucatan of Mexico. The crater harbors an armory of smoking guns, including shocked breccia clasts similar to shocked rock fragments found world-wide, tektite-like glasses, a pronounced iridium anomaly, and a radiometrically estimated geological age of 65.2 Ma, which matches the ages of world-wide K-T boundary samples with tektites. The crater suggests a bolide of some 10 km in diameter. If the impact were at an angle, presumably more material would be spattered into the atmosphere, but it is clear from the world-wide iridium anomaly that winds could have spread the calamity throughout the earth.

We at present can only speculate the possible biological consequences. The dust cloud would exist for a time sufficient to severely disrupt climate by cutting off all light, and temperature might have been expected to drop precipitously. A stable oxygen isotope anomaly at the boundary gives evidence for a sudden temperature change. The impact should therefore

Figure 1 Change in the number of marine and terrestrial taxonomic families throughout Phanerozoic time. Arrows point to times of mass extinction. Reproduced from Sepkoski Jr. JJ (1984) A kinetic model of Phanerozoic taxonomic diversity III. Post-Paleozoic families and mass extinctions. *Paleobiology* 10: 246–267. This estimate of standing diversity is biased with regard to variations in intensity of sampling, publications, and representation of specific time periods in terms of rock volume.

Figure 2 A more recent analysis of extinction rate of combined marine and fossil taxonomic families, based on recent compilations of a broad range of specialists. Reproduced from Benton MJ (1995) Diversity and extinction in the history of life. *Science* 268: 252–258.

have affected all organisms dependent on light and warm temperature. Deep-water forms not so dependent on light or warm temperature, such as nuculid bivalves, would be expected to survive. Alternatively, a hot plume emanating from the impact site could have accelerated the production of nitric acid, causing a world-wide shower of acid rain that might have poisoned the upper ocean.

Can extraterrestrial impacts be used to explain other major extinctions? The results are mixed. Positive and negative evidence for an iridium anomaly has been found for the Frasnian-Famennian (Late Devonian) mass extinction, but George McGhee and colleagues found that the extinction itself was spread over at least 7 My and climatic effects are evident. Solid evidence for impacts unfortunately postdate the

Frasnian-Famennian event. There seems to be no iridium anomaly associated with the terminal Ordovician extinction. A similar iridium anomaly in sediments of 34 My of age occurs simultaneously with the disappearance of five dominant radiolarian species, and at the general time of a mammalian extinction, but the larger picture of biotic change across this boundary is gradual, with no suggestion of a catastrophe. We are therefore left with the End-Cretaceous extinction to consider.

The Alvarez theory has one strong and other weaker predictions. (1) Extinctions must follow or coincide with the impact. (2) One might also expect many groups to die off instantaneously, but a less catastrophic change in temperature and light might have an effect that would be prolonged. (3) Finally, groups more prone to light stress or temperature increase would be more vulnerable (e.g., phytoplankton vs. deep-water deposit-feeding benthos), because an impact might likely spew dust into the atmosphere, lowering world temperature. The response of the sensitive groups should be geologically instantaneous.

As in most other mass extinctions, the end of the Cretaceous was preferential as to organisms affected. Groups associated strongly (Foraminifera, coccolithophorids) or weakly (ammonites) with the water column suffered most strongly, whereas benthic forms (e.g., bivalve mollusks) generally suffered less. Members of food webs less dependent on plant material (marine deposit feeders, scavengers, stream inhabitants, and small insectivorous mammals) suffered less than the strict herbivores. The relative success of sediment-feeding invertebrates relative to suspension feeders may be due to their occurrence in deeper waters.

There is also an apparent thermal bias in extinction at the K-T boundary. S. M. Stanley found that mollusks and Foraminifera in the tropical Tethyan sea suffered large-scale extinction, and were replaced by higher-latitude contemporaries. The question of timing is more confusing. Coccolithophores and non-globigerinoid Foraminifera disappeared so precipitously (and simultaneously with the iridium anomaly) that chalks give way to clastic sediments in a knife edge contact in several geological sections. In the chalk of Denmark, the Maastrichtian fauna, dominated by brachiopods, disappeared abruptly, with no prior warning in terms of reduced diversity, or early extinction of specialized forms. The sediments above the chalk are clayey and indicative of anoxic conditions. They also have a spike of iridium. Turbidity, loss of an appropriate sediment, and anoxia may all have contributed to the abrupt extinction. Radiolitic and hippuritid rudists bit the dust during a period of flourishing radiation. The current evidence suggests that Cretaceous vertebrates also bit the dust at the boundary, but preservation is probably too spotty to tell whether it is sudden in any respect.

Unfortunately, the larger story is not nearly so simple. Some fossil groups, including land plants, inoceramid bivalves, and ammonites experienced major extinctions or reduced speciation rates several million years before the impact occurred. The rudistids, cone-shaped bivalves that often formed Cretaceous reefs, died relatively suddenly, but well before the very end of the Cretaceous. Most embarrassing for the impact theory, the fresh-water biotas seem to have emerged unscathed. One would have thought that organisms such as turtles and crocodiles would be most vulnerable to a major extraterrestrial impact.

The dinosaurs represent an interesting case. The dinosaur fauna of the Late Maastrichtian included fewer than 20 species in 15 genera and 10 families, chiefly in the North American Western Interior. There is no good evidence, however, that the dinosaurs were declining steadily toward this low number in the last 9 My of the Cretaceous. It may well be that, although the dinosaur fauna was a remnant at the end of the Cretaceous, their demise was nevertheless caused by the impact.

The biogeography of extinction in the End-Cretaceous provides some insight. Maastrichtian planktonic foraminifera disappeared suddenly at the K-T boundary in middle and low latitudes. At high latitudes, however, a number of groups survived unscathed into the Danian, the beginning of the Paleocene epoch. The rudistid bivalves, associated largely with tropical and sub-tropical waters became extinct toward the end of the Cretaceous, but otherwise there are no differences with latitude in bivalve mollusk extinctions.

The sharpness of the boundary for any group is clouded by the imperfections of preservation. If the ranges of certain groups fail to extend all the way to the K-T boundary, then it is possible that perfect preservation would have given us a far different picture. Many western Tethyan ammonites appear to become extinct below the boundary but Charles Marshall and Peter Ward demonstrated that the confidence limits of a number of lineages allows the possibilities that poor preservation is the reason why some fossil ranges fail to continue right to the K-T boundary. Of course, this does not necessarily prove that the species became extinct at this time, they could have become extinct before or after. The analysis does exclude being sure that the geological range should be read literally. N. MacLeod performed a similar analysis with Upper Cretaceous foraminifera and found out that the ranges are compatible with a sudden extinction. They also, however, are compatible with many other possible scenarios. Some groups penetrate the boundary and it appears that there is good evidence that the fossils were not reworked up into the Danian by erosion and bioturbation.

In a mass extinction, we would love to have a single cause to explain extinctions, but, like the Permian, there may be several interacting and a succession of climatic changes that caused a range of extinctions.

1. In the Late Maastrichtian, sea level decreased by 150–200 m, making a hypothesis of increased terrestrial seasonality compatible with the ultimate disappearance. Just below the K-T boundary, sea level suddenly rises.
2. Temperature dropped.
3. The Deccan volcanics in India, enormous in scope, probably spewed a variety of substances that strongly affected the atmosphere and might produce effects resembling those of a bolide impact, but the activity probably predated the K-T boundary.

The evidence suggests that there may be more than one process at work in causing major extinctions. The evidence from land plants, dinosaurs, and many mollusks points to a change in conditions well before the Cretaceous-Tertiary boundary. Most notable are groups such as inoceramid bivalves and some of the ammonites that seem to be tracking an environmental deterioration before the termination of the Maastrichtian, or final Cretaceous stage. This would violate the

fundamental prediction that extraterrestrial events should be followed by and not preceded by, extinctions. But the iridium layer, plus its associated faunal disappearances, cannot be reconciled with any hypothesis of gradual climatic deterioration. There clearly was a sudden extinction at the K-T boundary, but it was focused on lower latitude microplankton; we can only speculate about suddenness of extinction in other groups. We are left with a compound hypothesis, at least for the proximate cause of the totality of End-Cretaceous extinctions. It has been suggested that the majority of strong extinction events in the Mesozoic and Cenozoic were at times when the major episodes of volcanism coincided with a bolide impact.

Complexity also characterizes the Permian extinction. It makes sense that sea-level drop was an important factor, operating by the effect of reduced habitable area and reduced environmental heterogeneity, but we have to reconcile the precipitous change in sea-level coverage in the last stage of the Permian, with the pattern of extinction, which was initiated earlier than the sea-level drop. Also, the extinction seemed to concentrate on certain ecological groups, particularly tropical forms at the end, but it affected high-latitude groups earlier in the Permian. Most discouraging of all, what if the extraterrestrial influence occurred in a series of impacts, as has been argued to be possible in the Frasnian-Famennian (End-Devonian) extinction, rather than as one big bang? Without a series of signals (e.g., a series of definitive iridium spikes of extraterrestrial origin), such a hypothesis is very speculative.

In conclusion, there is credible evidence for the role of an extraterrestrial object in causing extinction in the End-Cretaceous. Although other extinction factors might have been at work in the Late Cretaceous, extinctions occurring before the time corresponding to an extraterrestrial iridium anomaly do not falsify the impact hypothesis. At any time in the record, *some* groups must be declining. Even if we accept the impact as a source of some extinction, the Cretaceous still appears to be a compound event, as environmental change and the pace of extinction both accelerate before the K-T boundary. Isn't it bad luck that a large asteroid happened to smack into the earth just as sea level was changing as much as it did in the whole of the Phanerozoic? Several other mass extinctions also seem to be complicated, and were probably associated with changes in climate and sea level (that are probably interrelated). Anoxia may also be an important cause of mass extinctions, as witnessed by the extensive development of black shales in certain periods. What is lacking at present is a credible evaluation of the relative effects of these factors.

Long-Term Consequences of Mass Extinctions

In one obvious respect, mass extinctions had long-term consequences. Major groups of organisms were lost, meaning that ecosystems would never be the same. At the end of the Paleozoic, we lost trilobites, rugose and tabulate corals, orthid and productid brachiopods, and other groups, which changed the character of marine communities forever. Of course, we lost the ammonites and dinosaurs at the end of the Mesozoic. As mentioned above, the loss of relatively simple Paleozoic bottom communities gave way to Mesozoic communities

which were dominated more by burrowers and effective predators.

After major mass extinctions, paleontologists have noticed a brief period of acceleration of diversification, as if ecological space was being filled with diverse groups that replaced recent extinctions. Still, local diversity after the Permian extinction was often sparse. Andrew Krug and colleagues demonstrated that the End-Cretaceous extinction was followed by a brief acceleration of diversification, which was in turn followed by an uptick in origination rates of bivalve mollusk groups that persists to the present day. The explanation for this increase is still obscure but might relate to further increases of appearances of predators during the Tertiary period.

Biogeographic Aspects of Extinction

Some of the Phanerozoic changes in taxon richness can be related to a large degree to changes in the degree of provinciality. If we take the species-area effect as given and constant, it is easy to calculate that, as one large province is divided into two, reductions of the area are more than compensated by the increased total species richness as long as the dispersal between areas is limited. Thus a temporal increase in provinciality results in an increase of total biodiversity and a reduction results in a decrease. Major world-wide deterioration of climate (e.g., world-wide cooling, increase of seasonality) might be an example of a time when provinciality might decrease.

The Silurian period, for example, was one of extreme cosmopolitanism, with one province of approximately 90 articulate brachiopod genera in the North Silurian Realm. In the Ludlow (Upper Silurian), two provinces can be delineated, with about 90 genera in each province. In the Devonian, Arthur Boucot found that the number of provinces increased to six; the total number of articulate brachiopod genera increased to about 350 on average. During the Frasnian (Middle Devonian), this provinciality decreased relatively suddenly, and generic richness returned to 93.

The onset of the Permian extinction was also marked by a decrease in numbers of provinces, and the Early Triassic marks a nadir of provinciality in the Phanerozoic. During the end of the Paleozoic, geographically restricted bivalve genera succumbed before more wide-spread genera, suggesting that the overall environmental change was filtering out those forms that define provinciality in the first place. Norman Newell argued that the extinction was related to the major fall in sea level. Shallow marine seas were reduced from a coverage of 40 percent of their possible extent in the Early Permian to less than 15 percent in the latest Permian and then expanded to 34 percent in the Early Triassic. James Valentine and Eldredge Moores speculated that reduced rates of sea-floor spreading may have been responsible for a lowering of ridge activity, depression of deep-sea bottoms, and the consequential large-scale marine regression. The significant reduction in area, coupled with continental assembly of Pangaea at the end of the Permian may have increased extinction rates, and would have homogenized the fauna due to the possible presence of more inter-shelf dispersal possibilities. In contrast, the Pleistocene reduction of area covered by the sea was far lower and on the basis of area alone; the modest marine extinctions

are therefore not surprising from this point of view. Area reduction itself might not be a potent agent of extinction. Sea-level drops would hardly affect the shallow-water habitat distribution of oceanic islands, where most modern families are widely distributed. Sea-level drop may just be a correlate of another change.

The changing spatial relationships generated by continental drift and sea level fluctuations must have had important influences on climate. James Valentine's theory of climate change generated by continental assembly and fragmentation attempted to relate climate and sea level to sea-floor spreading. Periods of continental assembly were envisioned as times when interior continental climates were severe, affecting the continental shelf faunas. In contrast, times of fragmentation were times when the continents' climate was more moderate due to ameliorating marine conditions; this permitted the buildup of shallow-water diversity. Although the post-Permian expansion may fit this pattern, evidence from the Paleozoic does not seem to show an increase in continental fragmentation during the Early-mid-Paleozoic. Indeed, the continents were maximally fragmented and arrayed along the equator during the Cambrian. Continental drift and arrangement nevertheless have had profound effects on climate and probably extinction. During the Ordovician and Silurian Periods, Gondwana drifted southward from its Cambrian position at the equator, and came to rest on the geographic south pole. This coincides with the Late Ordovician glacial tillites that have been found in North Africa, and a large reduction in the degree of marine provinciality relative to the Early Ordovician. In the Cenozoic, the spatial arrangements of the continents about the Pacific and Atlantic Ocean made for a quite different climatic history. The North Atlantic was a more enclosed basin and was far more severely affected by the Late Cenozoic polar cooling. The Pleistocene initiated severe enough climates to cause a major molluscan extinction in the southeastern US Shelf, whereas Pacific American faunas showed no increased extinction.

The effects of increasing access between biogeographic realms can be illustrated by the large-scale interchange of mammals between North and South America after the Pliocene establishment of the Isthmus of Panama, following the disappearance of the Bolivar Trough marine barrier. Before the interchange, there was long-term stability in a number of mammalian families. As a probable result of North America's initial higher taxon richness, more taxa moved from north to south than in the reverse direction. In South America, where taxon richness now exceeded previous "steady state" levels by more than 50 percent, there was about a 70 percent increase in extinction rates. Descendants of the North American invaders participated in an evolutionary radiation, resulting ultimately in an overall richness higher than previous levels. Mammalian diversity is now higher in South America, in contrast to the situation previous to the exchange. This suggests that area does have an effect on regulating diversity, but evolutionary changes can impose a significant overprint on diversity.

Periodicity in Extinction, or Just Ups and Downs?

Periodicity of extinction or climatic change predicted by astronomical or geophysical theories would be the most

convincing way to establish a terrestrial or extraterrestrial cause of extinction. If extinctions are measurably periodic, it may be that only one credible cyclic theory would fit in the available pattern. The precedent for such an approach lies with the longstanding theories of the periodicity of Pleistocene glaciations. The Yugoslav astronomer Milankovitch theorized that Pleistocene glacial advances and retreats might be regulated by changes in high-latitude insolation, caused by cyclic changes in the earth's orbital eccentricity, tilt, and time of perihelion. A power spectrum analysis of temporal changes of abundance of Pleistocene planktonic fossils in oceanic cores corresponded well to climate changes estimated by stable oxygen isotopes and to periodicity peaks predicted by the Milankovitch theory.

A number of studies in recent years have taken up this theme and related these cycles to sedimentary cycles, including some of the classic mid-continent alternations of carbonate and mudstone. Many of these cycles occurred during times when there was no significant amount of continental glaciation, and represent transgressive-regressive cycles (rises and falls of sea level). For example, sedimentary cycles in the lacustrine Early Mesozoic supergroup correspond to periodicities of approximately 25,000; 44,000; 100,000; 130,000; and 400,000 years. These periodicities, in turn, correspond to those expected from celestial processes, such as the precession of the equinoxes, the obliquity cycle, and the eccentricity cycle. Cyclic processes such as the precession of the equinoxes may have driven continental heating cycles that rearranged wind and climate.

Milankovitch climatic rhythms also appear in Mid-Cretaceous black shale sedimentary cycles. These cycles consist of alternations of carbonate and shale, with intervals of highly oxidized (red) and highly reduced (black) strata. They are particularly interesting, as they occur in marine sequences and must have reflected periods of ocean bottom anoxia, alternating with vigorous bottom mixing and high productivity in the water column. On an even smaller scale, El Niño-La Niña cycles and the North Atlantic Oscillation whose forcing mechanisms of periodicity are not well understood, are known to cause cycles of benthic abundance in coastal communities and in small bays and fjords, such as the Swedish Gullmar Fjord.

The earth's history has been dominated by large-scale changes in climate, arrangement of continents, volcanism, and sea level. Alfred G. Fischer developed a theory connecting physical conditions with the overall pattern of Phanerozoic life. Global sea level was relatively high in both the Mid-Paleozoic and Mesozoic. Periods of continental breakup, when dispersed and thinner continents resulted in smaller ocean basins, would be associated with higher sea levels. Periods of continental aggregation, when continental crust was bunched up due to collisions and ocean basins were therefore more commodious, which resulted in lower stands of sea level. The temporal variation in granite emplacement matches the sea-level curve. This suggests a causal link between active continental fragmentation, volcanism, and sea level, an environmental condition of obvious importance to the world marine biota.

Fischer, a pioneer in global climate thinking with regard to the evolution and extinction of life, speculated on the presence

of a causal connection between changes in terrestrial vulcanism and global climate through the greenhouse effect. Increased volcanism may have liberated carbon dioxide into the atmosphere. As these periods were of higher sea-level stand, erosion would have been minimal, and loss of CO₂ in weathering would be suppressed. During times of low sea level, low volcanism would reduce the liberation of CO₂, and increased weathering would consume CO₂. Thus, the Mid-Paleozoic amelioration was associated with high CO₂, which, in turn, caused greenhouse effect and an increase of surface temperature. The end of the Paleozoic witnessed the termination of such conditions, and an "icehouse effect" resulted in a deterioration of climate mainly at high latitudes. It is not clear whether these cited fluctuations are irregular temporal changes or regular oscillations.

In time of extraordinary paleontological excitement, that, regrettably, has passed, David M. Raup and John J. Sepkoski reported a periodicity of about 26 My in the occurrence of extinction peaks of taxonomic families. Analyses of genera produced an even better periodic signal. To consider an extinction important, Raup and Sepkoski used a threshold level of 2% minor variations on this criterion change the periodicity to an average time of as much as 30 My between peaks, but the time between specific peaks varies substantially.

A number of celestial cycles have been suggested to explain the cyclicity. Of course, the most interesting ones are those that would cause rains of extraterrestrial objects on the earth or major changes in climate. So far, no theory works very well and it has also been suggested that a number of random models can explain the presence of cycles. This issue has not been settled yet and if the cycles are real, there is great hope that they can be related to an extraterrestrial source. Right now, the variation in extent of extinction and the average time between extinctions are not definitive enough to corroborate any models, which usually involve impacts of extraterrestrial objects such as asteroids or comets. An independent survey of extinctions supervised by Michael Benton failed to corroborate the presence of extinction periodicity. Alroy's more recent analysis also fails to find such periodicity.

Background Extinction and Turnover

Normal Extinction?

The great spans of geological time between mass extinctions also witnessed significant appearances and extinctions, but at lower frequencies. The temporal pattern of such extinctions is not clear. Arthur Boucot suggested that periods of several million years are often dominated by a set of ecologically distinct species, whose coordinated extinction might be followed by the invasion or evolution of a new set of ecologically similar forms. In recent years, a number of studies have shown that turnover (including extinction) is common at this temporal scale, but the exact pattern is variable. In some cases, periods of relatively low extinction are punctuated by high rates of a wide range of distantly related taxa, which are correlated with local environmental change such as basinal sea-level change. Other studies, however, show rather high extinction and appearance rates with no punctuations in

extinction. This is a field that needs to be explored with far more data collection and studies of environmental reconstruction before we find any pattern.

At this smaller scale of extinction, some of the same mechanisms as mass extinction may be in effect. Sea level rise and fall, climatic change, and other factors can operate on a smaller scale to cause extinction. At this scale, however, biological factors may be of great importance. Biological factors in extinction might include

1. Competitive displacement by an invader;
2. elimination by an overwhelming predator or herbivore;
3. spread of disease.

Some of these factors may have been involved in a worldwide extinction of the so-called megafauna, a group of mammals and large flightless birds that disappeared at the end of the last glacial advance. The extinction involved large marsupial mammals and large flightless birds, the renowned Irish Elk, large elephantine forms, saber-toothed marsupial, and placental cats, among others. It is possible that human hunting is the cause of these extinctions, but mobile human populations may also have brought novel diseases as they spread around the planet.

Declining Extinction Rates

Sepkoski's extraction from the fossil database of statistical entities known as evolutionary faunas produced the fascinating result that the so-called evolutionary faunas (EF) are less and less prone to extinction as we approach the present. In the Ashgilllean and Frasnian extinctions, for example, the more ancient Cambrian EF suffers more than the Paleozoic EF. In the Permian and Norian extinctions, the relatively older Paleozoic EF suffers more than the Modern EF. The successive evolutionary faunas also have progressively lower turnover (appearance plus extinction), which may make for increasing stability.

A class of distinctly lower family-level extinction rates decline during a long Paleozoic period of fairly constant taxon richness. To keep a steady state, a decline in extinction must be matched by an overall decline of originations, which has also been found. Why should family-level extinction and origination rates decline over geological time? There is no simple solution, although it is tempting to believe that taxa over time have evolved more and more resistance to extinction including reduced competition with other groups. Given the vagaries of extinction and the fact that extinction is usually an overwhelming process, driven by habitat loss, wide-spread marine anoxia, and other factors, this idea appears to be far fetched.

There may be an explanation to declining extinction that is a bit more mundane. Extinction might have declined as a result of the ratio of species numbers per family, which has been increasing steadily since the Mesozoic. If a family's representation in the world biota increases in number of species and its consequent ecological and geographic coverage, then the probability of family-level extinction may decline.

This explanation still does not provide a satisfactory answer to the decline in originations, which also decline over the same time period. Such a decline implies a long-term

reduction in the production of novelties sufficient to define taxonomic families. In other words, the rate of origin of morphological diversity has decelerated over time. Two concomitant processes may have contributed to this decline in origins of basic morphological diversity. A general filling in of resource space may have made it difficult for wholly new forms to take root later and spread. Our world may very well be the tangled bank conceived by Darwin.

Extinction and its Relation to Diversity

One of the most fascinating questions in ecology is the limit to which species numbers interact with the appearance of new competitors. The ecologist G. Evelyn Hutchinson first posed this problem in his landmark paper "Homage to Santa Rosalia or Why are There So Many Kinds of Animals?" Do all of the species that currently exist fill up available ecological space, creating a maximum of biological diversity? If so, what would happen if a biological crisis caused an extinction? Would diversity increase and fill in the gaps of ecological exploitation of resources generated by the extinction? This problem would arise for both mass extinctions and background extinctions. A very interesting observation by Arnold Miller and John Sepkoski showed that the number of genera of bivalve mollusks were increasing steadily from the Mid-Paleozoic through

the Tertiary. But there were conspicuous times when diversity dropped only to seemingly recover to match the ongoing trend. This may not support the idea that there is really a limit to the number of bivalve species that can be supported, because they were steadily increasing, but it does suggest that diversification is dependent on extinction and accelerated following occasional major drops. In a study of the relationship of diversity levels to rates of diversification during several mass extinctions, Michael Foote has shown that the rate of diversification increases at lower levels of diversity, which suggests that the diversification of life is dependent on standing diversity as Hutchinson would have argued. But Foote could find no obvious pattern relating extinction rate to diversification, despite other previous contrary results found in another study. This subject requires much further study. Alroy's general analysis suggests that extinction might play a role in diversification. (Figures 3 and 4).

To summarize, extinction in the fossil record reveals the following main points.

1. Mass extinctions caused world-wide precipitous loss of species, over a wide variety of taxonomic groups and habitats.
2. Environmental change in mass extinctions overwhelm the ability of a species to survive by profound changes in the environment over the whole species range.

Figure 3 "Supercycles" of the Phanerozoic, postulated by Fischer. Sea-level curve is superposed on a diagram of granite emplacement, times of glaciation, times of biotic crises (numbered) as determined by N. D. Newell, and a general estimate of climate, characterized by either icehouse (I) or greenhouse (G) conditions. (modified from Fischer, 1984).

Figure 4 Total numbers of marine animal family origins and extinctions per geologic stage (Reproduced from Hoffman A and Ghiold J (1985) Randomness in the pattern of 'mass extinctions', and 'waves of origination'. *Geological Magazine* 122: 1–4.).

3. The major mass extinctions eliminated a very large majority of the species on the planet and caused major reorganization of the world's biota.
4. In many cases, extinction appears to be selective with regard to ecological characters of the groups that survive, but in others one cannot identify any traits that make a group more resistant to extinction than others.
5. A distinctly lower level of extinction can be extracted from an analysis of the fossil data. This type of extinction might be a smaller version of mass extinctions, with relatively low rates of extinction punctuated by major regional environmental change driven by sea-level changes. Lower-level extinction rates appear to decline toward the present day. The explanation for this is unclear, but it may just be an artifact of the way taxonomic groups are classified into species. More recent taxonomic families have more species and more species-level extinctions would therefore be required to see the loss of a fossil family that occurred closer to the present day.

Glossary

Cryptic diversity Populations that are nearly identical to others in morphology but have significant differences in their DNA sequences, indicating isolation for an extended period of time; these represent unique evolutionary lineages that should be preserved.

Emerging disease An infectious disease that has newly appeared in a population or that has been known for some time but is rapidly increasing in incidence or geographic range.

Exotic species Organisms living in habitats where they do not occur naturally.

Metapopulation Collection of local populations linked through emigration and dispersal whose long term survival depends on the shifting balance between local extinction and recolonization.

Taxonomist Scientist whose work involves the discovery, description, and classification of life forms, based on the Linnean hierarchical system.

Introduction

Global declines of amphibians refer to the phenomenon of the population declines and even extinctions of amphibian species around the world. Assessments of the world's amphibians (Stuart *et al.*, 2004, 2008) found that nearly a third of the known species of amphibians are globally threatened with extinction and that at least 42% of known amphibian species are experiencing population losses. The rapidity and extent of these declines, far more dramatic than those described for birds, mammals, or reptiles, forecast impending extinction of numerous amphibian species during the coming decades. Many of these declines have occurred in protected areas where the causes have remained enigmatic. Other declines are due to obvious reasons, particularly habitat destruction, but the number of species experiencing enigmatic declines is increasing and these have caused the greatest alarm. Although climate change has been invoked as a potential contributing factor (e.g., Pounds *et al.*, 2006), evidence is mounting that epidemics of infectious disease may be primarily responsible for many of these catastrophic declines (Collins and Crump, 2009). The greatest threat is presented by a virulent fungal pathogen that can cause the infectious disease chytridiomycosis, which has decimated entire assemblages of amphibians worldwide. This pathogen, *Batrachochytrium dendrobatidis*, is responsible for what may well be the greatest disease-caused loss of biodiversity in recorded history, having caused population crashes or extinctions (often within a single year) of at least 200 species of frogs, even in relatively undisturbed, remote habitats. Compounding the crisis, amphibians suffer from relatively low levels of conservation effort compared to other vertebrate taxa. Although amphibians have survived a number of mass global extinctions throughout their 200 million year history, the speed and magnitude of this loss in amphibian biodiversity supports the idea that the earth may be now in the midst of a sixth mass extinction, similar to that which wiped out the nonavian dinosaurs.

Amphibian Biodiversity

The world's living amphibians include over 6800 species placed in three distinct clades, the frogs and toads (Anura), salamanders (Caudata), and caecilians (Gymnophiona). Of the three groups, frogs and toads exhibit the most varied reproductive modes and habitat associations and comprise the majority of amphibians (over 6000 species). Salamanders and caecilians, also diverse, have fewer species and are more restricted in distribution, but are still widespread (more than 600 species and nearly 200 species, respectively, based on the online resource AmphibiaWeb 2010). Most of the world's amphibian diversity occurs in the tropics, especially in Central and South America; other amphibian biodiversity hotspots include sub-Saharan Africa, Madagascar, Sri Lanka, SE Asia, New Guinea, and Australia (Figure 1). Salamanders are generally found in North Temperate regions, where all 10 families occur, but the largest family (Plethodontidae) is well represented in tropical America, where more than 40% of all salamander species occur. Salamanders are especially abundant in North America, whereas caecilians are restricted to tropical regions. In contrast, frogs range in distribution from the Arctic zone to the southern tips of South America and Africa.

Amphibians are often characterized as tetrapods with aquatic larvae and terrestrial adults, but alternative life histories are common. Some species of the three main amphibian clades are permanently aquatic. In contrast, other members of all three clades (including a majority of the species of salamanders and caecilians and more than a thousand frogs) are strictly terrestrial and lack aquatic larvae; eggs well provisioned with yolk are laid on land and develop directly into miniatures of adults. Some members of all three amphibian clades are live-bearers, giving birth to metamorphosed young that have been nourished during development in the reproductive tract of the female. Some salamander species never metamorphose, but remain aquatic in gilled or semi-gilled states throughout

Figure 1 Global amphibian species diversity by country, visualized using density equalizing cartograms. Each country's shape is purposely distorted in proportion to the number of amphibian species per country area (square kilometer) using the cartogram technique after [Gastner and Newman \(2004\)](#). life. Frogs have evolved many unusual life histories that avoid aquatic habitats for depositing eggs or larvae, such as transferring eggs to male vocal sacs, to pouches in the skin of the back of females, or even to the stomach.

Most salamanders have the structure of a generalized tetrapod with four legs, a relatively short but flexible trunk, and a tail, but some are extremely elongated with very small limbs or only forelimbs, and some reach very large size – in excess of 1.5 m. Caecilians are limbless and their eyes are covered by skin or bone. Caecilians have high numbers of trunk vertebrae and are very elongated, but they either lack entirely or have an exceedingly short tail. Frogs are also tetrapods but have a more specialized form that generally enables jumping (although some species walk, hop, or burrow), because they lack a tail, have a very short and stiffened trunk, and have relatively elongated legs and feet.

Adult amphibians are effective predators and both salamanders and frogs have tongues specialized for rapid, long-distance prey capture. Caecilians generally feed on subterranean prey such as earthworms. Amphibians are represented in diverse aquatic and terrestrial ecosystems and frequently are important components of communities and food webs. In some ecosystems, they are the dominant predators, both in terms of numbers and total biomass.

Dimensions of the Problem

Geography

The geographic extent of amphibian declines is worldwide (see Fisher *et al.*, 2009 for a longer review). Areas most strongly affected are located in Central and South America, the Caribbean, the wet tropics of eastern Australia (Figure 2), and western North America (Stuart *et al.*, 2008). The islands of the Caribbean and Pacific have some of the highest percentages (up to 100%) of endemic species that are threatened or endangered, but have relatively few species. Less is known about the status of species in Africa and Asia. Nonetheless, some species-rich countries have alarmingly high percentages of threatened and endangered species (e.g., 70% for Sri Lanka, based on the online resource IUCN 2010). The first reports of massive collapse of amphibian faunas came from montane areas in Central America and Australia. The loss from the protected Monteverde Cloud Forest Reserve in Costa Rica of more than 50% of the amphibian species within the course of a single year (1987) was a profound shock, and included the first prominent extinction (the golden toad, *Bufo periglenes*). Collapse of amphibian fauna in montane and lower montane Central America and South America is ongoing. In Australia, declines began in the 1970s in southern Queensland and Tasmania and accelerated in the 1980s. In Europe, die-offs were observed beginning with Spain in the mid-1990s. Concern has been expressed over declines of frogs in the western US for many years, and in the 1980s and early 1990s population collapses were observed in relatively undisturbed areas such as Yosemite National Park. Amphibian declines have since been reported from many parts of the world.

Ecology

In characterizing the ecology of species that have declined, most attention has focused on high- or mid-altitude species that are associated with streams, have small ranges (implying higher habitat specificity), and low reproductive rates, but there are many exceptions. Species that have aquatic breeding habits and stream-dwelling tadpoles have generally experienced sharper declines than species that lay eggs on land and that develop without a larval stage (direct developers). However, direct-developing species are not exempt; in Puerto Rico, for instance, many species of direct-developing frogs have declined and some may be extinct.

Amphibians are important members of ecosystems, and their declines are likely to have diverse and as yet not fully understood impacts on communities and ecosystems. Amphibians are unique among vertebrates in that many have biphasic lifecycles that include both fully aquatic (larvae) and terrestrial or semi-terrestrial (adult) forms. This makes amphibians key components in both terrestrial and aquatic food webs. Aquatic systems are more productive than the surrounding terrestrial systems in some areas, and amphibians help to link these two types of habitats. Although larval salamanders are carnivorous, tadpoles (larval frogs) are generally herbivorous and play important roles in controlling vegetation levels in both lentic (still water) and lotic (flowing water) ecosystems. For example, streams that have lost tadpoles can become choked with aquatic vegetation. Tadpoles compete with aquatic insect larvae for food, and loss of tadpoles alters the macroinvertebrate community composition. Adult amphibians may prey on a variety of items depending on their size and lifestyle; burrowing caecilians generally consume earthworms, whereas terrestrial frogs and salamanders may consume anything from tiny terrestrial leaf-litter dwelling insects such as springtails, mites, and ants to other vertebrates (including other amphibians). Amphibian loss affects predator populations (e.g., snakes) and may also affect the population dynamics of prey taxa such as insects.

Systematics

Amphibian systematics is in a state of flux, adding to the challenge of assessing and tracking the scope of global decline. There are insufficient numbers of amphibian taxonomists, which hinders fundamental conservation assessments. Currently, amphibian taxonomists are concentrated in the more species-poor but wealthier countries; there is increasing recognition of the need for established resident taxonomists in species-rich regions. A new generation of taxonomists is developing in Asia and South America, but there are gaps in expertise in species-rich regions such as Africa. The marked recent increase in amphibian biologists has accelerated field studies in remote areas and discovery of many new species. Ironically, during a time of crisis for the world's amphibians, the number of described species has risen from 4000 in 1985 to over 6800 today.

Phylogenetic patterns of amphibian declines are not well understood. Some clades appear to be especially susceptible to declines. For example, frogs of the genus *Atelopus* from the highlands of lower Central America and the mountains of

Figure 2 Percent of threatened and endangered amphibian species by country visualized using density-equalizing cartograms. Country size is purposely distorted in proportion to the percentage of threatened and endangered amphibian species, not including introduced species using the cartogram technique after [Gastner and Newman \(2004\)](#). (Data sources: AmphibiaWeb (website accessed 17 November 2010) and IUCN (website accessed 30 September 2010).)

northwestern South America have been hard-hit by declines; nearly 80% of described *Atelopus* species have been classified as critically endangered or extinct. These species have stream-adapted larvae. Elsewhere stream adaptation is also associated with declines, suggesting a phylogenetic bias within the clade containing *Atelopus*. Although salamanders seem to show less evidence of declines than frogs, neotropical salamanders (both ambystomatids and plethodontids) are experiencing severe declines. The vast majority of tropical salamanders are plethodontids, members of a single clade known as bolitoglossines, and declines of Mexican and Guatemalan species have been well documented (Rovito *et al.*, 2009). Although a number of studies have found a phylogenetic component to amphibian declines, data from one of the best-studied amphibian mass mortality events in Panama indicated that decline and extirpation were random with respect to phylogeny (Crawford *et al.*, 2010). Assessing the amount of phylogenetic diversity lost in declines and extinctions is also complicated by the fact that the amphibian fauna is not fully known in many species-rich areas.

Factors Responsible for the Declines

Potential causes for the widespread declines of amphibians can be grouped into two major categories: (1) factors general to the overall biodiversity crisis, including habitat destruction, alteration and fragmentation, introduced species, and over-exploitation and (2) factors associated with amphibians that might account for declines in relatively undisturbed habitats. The first category includes relatively well understood ecological phenomena, whereas the second includes less well understood agents with complex underlying mechanisms, such as infectious diseases, climate change, increased UV-B radiation, chemical contaminants, and the causes of deformities. Habitat loss has played a major role, as has the infectious disease chytridiomycosis, but amphibian populations often face many simultaneous threats and synergistic interactions between different threats may exacerbate declines.

Habitat Degradation and Land Conversion

Perhaps the most obvious factor in the loss of amphibians is habitat degradation and land conversion. Although some amphibians are able to not only persist but thrive in urbanized or agricultural areas, many species require undisturbed (or relatively undisturbed) habitat. Loss of wetlands is a major factor in temperate zones, whereas removal of forests is the most serious threat in the tropics. Habitat fragmentation, where forest remnants persist but are separated by disturbed habitat such as pasture, is a serious issue for widespread species and in those that have natural metapopulation structures. Many amphibians, especially terrestrial species with direct development and no larval stages, are typically highly structured genetically and have cryptic diversity; in this case, habitat fragmentation leads to extensive loss of biodiversity as populations die out, even if species fragments persist. Human-induced disconnection between habitats used by different life history stages makes breeding

migrations risky and may account for some of the reason why species with aquatic stages are declining more than strictly terrestrial species. Some habitat changes are subtle and have unexpected effects. Fire suppression in parts of western North America has led to encroachment of forests into breeding sites, with the resulting increase in shade having negative effects on tadpole development in some species.

Habitat degradation from pollution from agricultural herbicides, insecticides, and fertilizers impacts amphibians with aquatic life stages, either directly or by synergistic interactions with other factors (Hayes *et al.*, 2010). Chemical pollutants can directly kill larvae at certain concentrations, but even sublethal concentrations can affect behavior, reproduction, and life history, and can reduce the food supply (Relyea and Diecks, 2008). In some species, stress can magnify the effects of chemical doses that would normally not be lethal. We remain far from having a full understanding of the impacts of additives by humans to the environment on amphibians.

Impact of Exotic Species

The establishment and spread of exotic species are major threats to worldwide biodiversity and there are many examples of amphibians being affected. Exotic species can affect amphibians as competitors, predators, and as vectors for parasites and diseases. Nonnative amphibians may have contributed to many of the declines of native amphibian species. The bullfrog (*Rana catesbeiana*) is native to eastern North America but has been transported around the world by humans, mostly for human consumption. In California, wild populations of nonnative bullfrogs now eat and out-compete red-legged frogs (*Rana draytonii*) and foothill yellow-legged frogs (*Rana boylei*), both of which are in decline. In the last several decades, nonnative bullfrogs have escaped from commercial frog farms, particularly in South America, and established wild populations in areas where native frog populations collapsed. Although many native amphibians are dying from chytridiomycosis, bullfrogs appear to be resistant and are thought to act as carriers for the disease.

In Australia, sugar cane farmers introduced cane toads (*Bufo marinus*) in an effort to control insect pests, but the nocturnal cane toads do not control the largely diurnal pests. Since the first introductions in the late 1800s, cane toads have spread rapidly throughout eastern and more recently northern portions of Australia where they act as both competitors and predators of native amphibians, as well as apparently introducing pathogens and parasites. Cane toads produce toxins at all life stages, and ingesting cane toad eggs, larvae, or metamorphs is fatal to both larval and adult native Australian amphibians.

Another invasive amphibian species is *Xenopus laevis*, the African clawed frog, which is now widely established around the world. These fully aquatic frogs are prolific, highly invasive, and prone to *Bd* infection but resistant to chytridiomycosis. Like bullfrogs, African clawed frogs have been implicated in the spread of both chytridiomycosis and ranaviruses to native amphibians. They also out-compete native

amphibians, which decrease reproduction in ponds invaded by feral *Xenopus laevis*.

Fish are generally dominant species in aquatic systems and human-mediated introduction of fishes to new aquatic habitats has often had devastating consequences, especially for those amphibian species that evolved without fish predators. Fish-naïve amphibian species may fail to recognize predator cues or lack behavioral responses to avoid fish predation. Introduced fish such as mosquitofish, carp, and trout have been shown to prey on amphibian eggs and larvae. Trout are native to cold mountain streams in North America and Europe but have been widely introduced to every continent except Antarctica. In the Sierra Nevada of California, more than 99% of the lakes and ponds above 2,100 m were fishless prior to the mid-1800s. Since then, trout have been introduced into more than 90% of Sierra Nevada lakes for sport fishing. Mountain yellow-legged frogs, once the most common vertebrates in these high-elevation ponds and lakes, are adapted to life in environments without any fish and have declined dramatically with the introduction of trout. Field experiments showed that removal of introduced trout from entire lakes could lead to recovery of local mountain yellow-legged frog populations. However, soon after this discovery chytridiomycosis was detected in the Sierra Nevada and has spread rapidly, further endangering the last remaining populations of these species. Paedomorphic salamanders (which retain certain larval traits and remain aquatic into adulthood) can also be particularly vulnerable to fish predation. Another introduced aquatic predator known to feed on amphibian larvae is the red swamp crayfish (*Procambarus clarkii*, which is native to North America but has been introduced on all continents except for Antarctica and Australia) and is associated with amphibian population collapses in Portugal.

Fish compete with amphibians (and birds) for aquatic insect prey. Presence of introduced insectivorous fish such as trout in montane lakes of northern California was correlated with decreased diversity of native aquatic insects and far less insect emergence. Removing introduced trout from northern California lakes led to the recovery of invertebrate populations.

Introduced species can exert effects on native amphibians indirectly by altering the habitat. Exotic fish such as carp or tilapia can increase water turbidity in shallow water bodies, which decreases productivity and is thought to be one factor in the decline of native axolotls in Mexico.

Infectious Diseases

Infectious diseases have been associated with collapsing amphibian populations almost everywhere that amphibians occur (Fisher *et al.*, 2009; Gray *et al.*, 2009). Most of the reported amphibian mass mortality events have been associated with the emerging fungal pathogen *Batrachochytrium dendrobatidis* and viruses of the family Iridoviridae, but other agents such as bacteria, water molds, and trematode parasites have also been associated with varying levels of mortality and population decline.

Chytridiomycosis, an amphibian disease caused by the pathogenic fungus *Batrachochytrium dendrobatidis* (*Bd*), plays a

major role in amphibian population collapses in both protected and disturbed habitats around the world and has been called “perhaps the most virulent threat affecting vertebrates to emerge in recent years” (Hoffman *et al.*, 2010). Catastrophic *Bd*-related declines have occurred in Central and South America, Spain, Australia, and California (Collins and Crump, 2009). Chytridiomycosis is of great concern in general because it is the first emerging disease that causes declines, and perhaps even extinctions, of many species not otherwise threatened. Scientists debate whether *Bd* is a novel pathogen, with the spread to new host species and new geographical areas mediated by humans, or an endemic pathogen that has increased in virulence, possibly because amphibians have been rendered more vulnerable by environmental changes. When the fungal load reaches a critical threshold, it fatally compromises electrolyte transport, causing cardiac arrest (Voyles *et al.*, 2009). The ecology of *Bd* remains poorly understood but we do know that density-dependent host–pathogen dynamics are key components (Briggs *et al.*, 2010; Vredenburg *et al.*, 2010). Many questions remain unanswered: Is reproduction of *Bd* ever sexual? Are there resting life stages? How is *Bd* transported?

Viruses belonging to the family Iridoviridae (ranaviruses) have been associated with mass mortality in both frogs and salamanders, in wild populations as well as in captivity. Like *Bd*, spread of these viruses appears to have been at least partly mediated by humans via the global amphibian trade. Ranaviruses appear to have undergone recent host shifts from fish to amphibians.

Other agents contributing to amphibian declines include gram-negative bacterial pathogens; the best-known of these is *Aeromonas hydrophila*, which causes red-legged disease and has been responsible for local extirpations of wild ranid frogs in California and Rhode Island. Pathogenic water molds (*Saprolegnia* sp.) have been found to be responsible for local extinctions in some North American frogs, as well as massive egg mortalities in some European frogs, and to increase mortality in at least one North American salamander species. Trematode infestation has been implicated in limb deformities in the Pacific treefrog (*Pseudacris regilla*) and several other species of amphibians, and to cause tadpole mortality, but so far no major population declines have been tied to trematode infestations. Declines in the Wyoming toad (*Bufo baxteri*) have been attributed to both *Bd* and another parasitic fungus, *Basidiobolus ranarum*.

Human Exploitation

The impact of harvesting wild species for the global pet trade and for human consumption is of increasing concern (Schloegel *et al.*, 2009; Gratwicke *et al.*, 2010). Solutions to these global problems, which often are tied intimately to local economic conditions and traditions, ultimately depend on effective public education.

Factors Associated with Global Climate Change

Amphibians may be more sensitive to climate change than other vertebrates such as birds because amphibians are more

likely to show habitat and microhabitat specialization and because they are significantly less vagile. Many of the effects of climate change might be indirect, involving such factors as manifestations of disease or pathogen-host dynamics, and may involve interactions with other stressors (Blaustein *et al.*, 2010), making direct detection of impacts difficult.

Elevated UV-B radiation

Global atmospheric changes caused by anthropogenic activities are well documented and one result is a reduction of stratospheric ozone, leading to an increase in the amount of biologically damaging ultraviolet radiation (UV-B) reaching the Earth's surface. Increase in UV-B has been hypothesized to contribute to increased mortality rates in amphibians with the idea that this might explain enigmatic declines in protected areas. Tests of this hypothesis have focused mainly on comparing egg-hatching rates in species that lay their eggs in shallow, exposed breeding sites that should be subjected to high levels of UV-B. Field experiments have concluded that many species are sensitive, but others are not, even at high-elevation sites where the ambient UV-B dose is high. Interactions between UV-B and abiotic factors such as water chemistry are important in some instances. Synergism between UV-B exposure and stress from the risk of predation can increase tadpole mortality in a sensitive species by two-fold over the additive effects of exposure to either stressor alone. Also, not all species that are known to be sensitive to UV-B are in decline. Although UV-B may be involved in synergistic interactions with other factors (Bancroft *et al.*, 2008; Blaustein *et al.*, 2010), at this point it does not appear to be a major component of amphibian declines in general.

Temperature Variability and Amphibian Immunity

Elements of climate change are thought by some to make conditions more favorable for amphibian diseases and parasites (Pounds *et al.*, 2006), but the causal link between climate change and disease virulence is unclear and debated. The rapid spread of *Bd* appears to be sufficient to cause mass amphibian mortalities without invoking climatic change (Lips *et al.*, 2008). However, stress from climate change (in particular, increased temperature variability) may decrease frog immunity, making it easier for pathogens to cause death (Rohr *et al.*, 2008; Rohr and Raffel, 2010).

Threats from Shifts in Weather Patterns

Some species react to changes in climate by shifting their distributions either latitudinally or altitudinally (Rovito *et al.*, 2009). Amphibians, especially those in tropical regions, are narrowly distributed; often they are restricted to specific and narrow elevational belts on mountains that are themselves isolated. There may be no place to go when climates are warm or dry, except higher up the mountain. Species already at the top of such habitats literally are pushed off the mountain, into extinction. Other species may be limited in movements to the north or south by ranges fragmented by habitat conversion or by barriers such as rivers that effectively stop range expansion.

A documented effect of climate change has been the earlier breeding of some species in the northern parts of their ranges. The common frog (*Rana temporaria*) in Great Britain must advance the date of first spawning by three to five weeks in

order to accommodate increasing temperatures, but will only be able to advance by five to nine days (Phillimore *et al.*, 2010), so adaptation for this species and other amphibian species may fall well short of the challenge.

In Central America, the cloud line has risen several hundred meters, which apparently precipitated a drought of unusual severity in a high-elevation cloud forest in Costa Rica (Monteverde) in the late 1980s (Pounds *et al.*, 1999). This drought has been implicated in the disappearance of 20 of the 50 species of amphibians known from the site, including a local endemic, the golden toad, *Bufo periglenes*. But it is not clear whether this was the result of an exceptional event (an unusual dry season) or a more general effect, and chytridiomycosis has also been implicated in the disappearance of Monteverde amphibians.

Synergistic Effects

Many factors by themselves pose severe threats to amphibian survival, but synergistic interactions between factors can magnify the negative effects on amphibians. Many different synergistic effects have been suggested, likely posing major threats to the continued existence of numerous amphibian species (Pounds *et al.*, 1999; Relyea and Diecks, 2008; Blaustein *et al.*, 2010). For instance, the effects of infectious diseases may be greater in the presence of unusual weather conditions, elevated UV-B, or chemical pollutants, which may compromise amphibian immune systems. Unusual weather conditions (particularly drought) might enhance the impact of different stressors. The link between climate change and pathogen growth conditions in Central America may be enhanced by the presence of high environmental loads of pesticides in the area, which may be an additional stressor. Hierarchical approaches to defining the causes of declines (Hayes *et al.*, 2010) hold promise for identifying critical factors that might be subjects for further study.

Challenges and Opportunities for the Future

Many of the most dramatic instances of declines have occurred in protected areas, such as the great national parks of the Sierra Nevada of California, the Monteverde Cloud Forest Preserve in Costa Rica, and protected areas in Australia, to give three prominent examples. Thus the standard conservation approach of purchasing and protecting land and habitats may not ensure survival, but remains an essential strategic component for maintaining ecosystem function. Conservation strategies must involve both specialist and generalist researchers with diverse talents in infectious disease ecology, reproductive biology, endocrinology, immunology, and pollution ecology, as well as knowledge of the natural history of affected species. *Ex situ* strategies may be essential in particular cases, but captive breeding is difficult and expensive and careful thought must be given to selection of candidate species (e.g., phylogenetic, ecological, and behavioral diversity should be represented). A greater understanding of synergistic effects is required in order to counteract the diverse threats facing this ancient group of organisms.

Mitigation of Habitat Changes

Habitat fragmentation is a cause of declines that might be mitigated by re-establishing habitat corridors and connectivity, such as vegetated freeway overpasses, reforestation, and road tunnels to facilitate wildlife movement.

Wetland restoration holds promise for recovery of some amphibian species. Wetlands are important components of the earth ecosystems, providing vital ecosystem services (i.e., water purification). Mitigation in wetlands not only benefits humans directly by helping restore clean water systems, but also provides important habitat for many species of amphibians.

Removal of Exotic Species

The removal of exotic species has been effective in restoring amphibian populations in some instances. For example, removal of exotic fishes has had positive benefits for amphibians in Spain, Chile, and in several areas within the United States. In California, removal of nonnative trout from entire lakes in the Sierra Nevada led to rapid recovery of threatened mountain yellow-legged frog populations. However, whether these population recoveries will translate into species persistence is undetermined; only 1 of 209 amphibian species examined (the Mallorcan midwife toad, *Alytes muletensis*) improved in conservation status due to mitigation of invasive species introductions (Hoffman *et al.*, 2010).

Attenuation of Infectious Agents

Disease ecology seeks to understand the mechanisms that lead to disease outbreaks in natural systems. Global trade, and thus the vast increase in connectivity between continents, has been linked to many of these outbreaks (Schloegel *et al.*, 2009; Gratwicke *et al.*, 2009). Precautions necessary to lower the probabilities of future outbreaks include limiting transport of diseases by use of disinfection and quarantine programs and by stopping human movement of disease vectors (i.e., live bullfrogs). Chytridiomycosis and ranaviral infections are now on the list of notifiable diseases (World Organization for Animal Health, Office International des Epizooties), meaning that all 177 member countries must report on the status of *Bd* and ranaviruses within their borders every six months.

There are a few glimmers of hope for amphibians. Despite the fact that most populations of mountain yellow-legged frogs have been decimated, a few with known infections of *Bd* have persisted for years. Some species of Australian frogs that survived epidemics of chytridiomycosis appear to be re-establishing themselves and to have relatively robust antimicrobial defenses.

Captive Breeding

Although some biologists view captive breeding as a last-resort conservation action, the IUCN endorses captive breeding as a proactive conservation measure, one that should be initiated while a species is still available. IUCN, through its Amphibian Specialist Group, sponsors the Amphibian Ark, which tracks *ex situ* captive breeding activities for amphibians around the world. However, captive breeding is costly and many hurdles

must be overcome (including getting a species to breed successfully in captivity and ensuring that disease is not transmitted) before captive-bred individuals can be reintroduced to the wild (Griffiths and Pavajeau, 2008).

Implications for the Biodiversity Crisis in General

Amphibian declines represent the leading edge of the extinction wave (Wake and Vredenburg, 2008). As humans continue to alter the environment on a global scale, amphibian declines may be the window into the future of what we can expect for global biodiversity: extinctions on a massive scale, well beyond anything we have ever experienced. Despite some local successes, current conservation efforts are insufficient to offset global biodiversity losses. Meanwhile, amphibian declines continue. Although the past decade has seen a dramatic increase in research directed to the multiple and diverse factors associated with declines and significant progress has occurred in many areas, challenges remain. Human activities are a primary source of the problems facing amphibians and, ironically, also the main hope for the future.

Latent Extinction—The Living Dead

Daniel H Janzen, University of Pennsylvania, Philadelphia, PA, USA

This article is reproduced from the previous edition, volume 3, pp 689–699, © 2001, Elsevier Inc.

Glossary

Agroscape The agricultural, ranching, and plantation countryside, with its roads, irrigation ditches, buildings, and so on. The agroscape stands in contrast to the wildland countryside that is not directly managed by humanity (though it is strongly impacted by it). The agroscape intergrades with wildlands in the form of woodlots, abandoned fields, poor soil sites, hedgerows, and edges of wildlands.

Living dead An individual stripped of the ecological circumstances that allow it to be a reproductive member of its population, but which is living out its physiological life. Living dead are most easily observed as large trees remaining on the agroscape, but they are also present in natural ecosystems.

Megafauna Large mammals that are wolf-sized, deer-sized, and larger. Commonly used in reference to the many species of extinct “Pleistocene megafauna” that 9000 years ago populated the New World. The elimination of this megafauna by hunting (of the herbivores) and starvation (of the herbivore deprived carnivores) was probably the first, and certainly the most dramatically irreversible, of the anthropogenic macroalterations of New World ecosystems. Today, of the extinct Pleistocene megafauna, only the horse remains—evolutionarily invented in the New World but surviving in the Old World until brought back as a gift from the Pleistocene by Spanish soldiers.

Introduction

The idea of the living dead has gradually emerged in my ecological understanding as I have lived past and around the majestic forest giants left standing as the agroscape creeps into Costa Rica’s forest ecosystems over the past 4 decades (Figure 1 and Janzen, 1986a, 1986b). This creep gradually converts the forest to an agroscape of pastures, fields, and roadsides dotted with the occasional adult tree but few or no juveniles. This is an agroscape where a magnificent flower crop now stands bee-less, an agroscape where fruit crops lie rotting below the pasture tree, an agroscape where tree seedlings wither in the dry-season sun or are turned to smoke in the dry-season anthropogenic fires.

I begin this article with a focus on adult large trees and use familiar examples from the Costa Rican countryside. To create breadth, I suggest that you join these verbs with the nouns from the ecosystems you know. This is a conservation biology question, but it applies to more than that, and it applies across the once-forested tropics as well as elsewhere.

Looking across the tropical landscape, the eye is greeted by stately single trees (Figure 2), by patches of forest, by the blaze of a colorful flowering episode. Put an inventory to the plant species in a field, in a valley, in an ecosystem. All these species appear in the list. All is more or less well, we conclude, as 96.4% of the species that were here 50 years ago are still present. But are they? How many of them are living dead, part and parcel of latent extinctions?

We live a perceptual lie as we bustle about our agrosapes. That single stately green *Dipteryx* or *Hymenaea* or *Swietenia* or *Enterolobium*, standing in a field, pasture, or roadside, is often just as dead as if it were a log in the litter or the back of a logging truck. That tree was birthed in some favorable circumstance, a circumstance for pollination, seed dispersal, seed germination, and sapling survival.

But one or more of these circumstances is now gone. It was carried away with the forest, put on the hunter’s table, pesticated out of existence, or global warmed into oblivion. The long-lived tough adult lives out its physiological life, in the absence of the carpenter with a chain saw, but it is evolutionarily dead. Its pollen no longer flows to other members of the population, its seeds are no longer carried away from seed predators, or its seeds are no longer carried to a favorable site for seedling growth and sapling survival to adulthood.

But because the adult lives on, we are lulled into thinking that the environmental damage really is not all that bad, that extinction has not already occurred. If we can still show the tree to our children, it seems not to be extinct. It is so big and green and strong. Every year we see its flowers, and maybe we even see its fruits on the ground below. And after all, it has clearly weathered all that we have thrown at it. What ever can the matter be?

Humanity’s interaction with the world’s ecosystems has an enormous perceptual element. We act on what we perceive, be it threat or opportunity. Much of our conservation pragmatics and understanding is based on our knowledge that we really are losing species, losing ecosystems, losing the capacity of the environment to absorb our footprints. But that knowledge comes from what we see and measure. If all members of a tree species were to have the trait that each abruptly falls over dead the moment that it ceases to be a reproductive member of its population in its ecosystem, there would be far stronger alarm cries across the tropics about extinction rates and realities. If trees, the largest organisms on most of our landscapes, were very short lived as compared with humans, there would be less of a perceptual problem—though just as large a conservation problem.

When the terrestrial world was covered with forest ecosystems, the single tree left standing in an aboriginal cornfield

Figure 1 Living dead trees isolated in pasture at the edge of the agroscape (background) as it creeps into old growth forest (foreground). Los Naranjos, Sector Cacao, Area de Conservación Guanacaste, July 29, 1987.

Figure 2 A living dead *Terminalia* tree stands in silhouette, left behind as the rain forest was cleared around it, the natural tree falls in which its seedlings might have survived long since removed. Rincon Rainforest, Area de Conservación Guanacaste, January 6, 2000.

may well have been living dead, but the population from which it was derived was not usually at risk of anthropogenic extinction, unless perhaps dependent on a seed disperser targeted by that aboriginal population (Janzen and Martin,

1982). But when the agroscape is dotted with living dead in the wake of contemporary omnipresent ecosystem alteration, latent extinction is very real. A tree species may be ranked as “common”—meaning visible from a car window along many roads—yet be effectively extinct in a county, state, or region. And since the agroscape now stretches from horizon to horizon, the plant may well be absolutely extinct, since all of its former range may be populated by living dead.

Deforestation and the Living Dead

The forest need not be removed to convert trees to living dead. It is just that when the forest is partly removed, there is a very high chance that this alone will ecologically deprive many individuals of the remaining tree species sufficiently to convert them to living dead status. And, it certainly leaves the living dead very visible.

But even when the forest is left in place, that is no guarantee of a healthy tree population. When the Pleistocene hunters and their carnivorous helpers hunted out the neotropical mastodons and gomphotheres, the glyptodonts and camels, the ground sloths (Janzen, 1983b; Janzen and Martin, 1982), they did not do it by forest clearing. For decades to millennia after this 9000-year-old event, many of the remnant individuals of the tree populations that these big mammals dispersed (Figure 3), and for which they created safe sites for seedlings by their browsing and trampling, would have been living dead scattered in the forest.

If some particular species—a pollinator or dispersal agent, for example—in the forest is extinguished, by whatever cause, there will often be surrogates and alternates that will assume, in some form, some portion of the “role” of the extinguished mutualist. The tree species will live on, albeit in some other ecological morph, and therefore in some technical sense will not be extinct. The tree that was “dependent” on the

extinguished species will not, then, be living dead. But the devil is in the details. We need to go case by case. The suite of interactants with a tree species generates a given seed shadow, pollen rain, sapling demography, and microgeographic distribution. Remove one species of interactant. The entire n-dimensional hyperspace shifts in this or that direction. In some places this is toward eventual extinction, in other places it is just a change in demography and microgeographic distribution.

The history of any surviving species is that it must have survived thousands of such handoffs from one mutualist to another, from one moment to the next (e.g., Hallwachs, 1986). What bumps individuals into the category of living dead is the serendipitous event of losing irreplaceable partners. Humanity has a way of removing not only partners, but whole suites of them, as well as altering the physical environment. Our thoroughness and omnipresence creates ecological irreplaceability. Yes, when we lose one ground sloth, a glyptodont picks up some of the slack, though the tree is now a different beast. And at some time, likely as not, some new slothoid arrives by evolution or immigration over the millennia. But lose all these big mammals at once, and the result is guaranteed to be large arrays of living dead.

We have all been nourished by the marvels of evolutionary understanding, leading to the temptation to wonder if rapid evolution will not resuscitate a living dead population, if not many of its individuals. Novel pollinators, dispersal agents, fruit morphology, flowering phenology—all could save the day. In theory yes, but in reality not on the timescales ordained by humanity's charge across the landscape. How long will it take to evolutionarily reinvent a neotropical herbivorous/frugivorous megafauna? Fracture the remaining forest, with its living dead, into small ecological islands (also known as national parks and reserves). Thereby create ideal circumstances for rapid and novel evolution. We still cannot expect natural selection to create a mastodon from a white-tailed deer

in anything like the speed required to be an antidote for neotropical rain forest anthropogenic alteration, beginning with the megafauna extinctions.

Certain kinds of habitat destruction are compatible with some tree natural histories. Two common trees, the guanacaste (*Enterolobium cyclocarpum*, Fabaceae) and jicaro (*Crescentia alata*, Bignoniaceae), owe their contemporary prominence on the Mesoamerican Pacific coastal landscape to a particular kind of habitat destruction. For both, large mammals—such as free-ranging horses—swallow the seeds while eating the content of indehiscent fruits fallen below the parent tree (Figures 3 and 4), and later defecate them in open sunny habitats (Janzen, 1981, 1982a, 1982b). Forest clearing unto brushy pastures and scraggly roadsides, populated by widely circulating working horses, maintains a healthy population of reproducing guanacaste and jicaro trees in a precarious balance with humanity.

What did these trees do before the Spaniards brought the horse back from its Old World refuge after its neotropical extinction by Pleistocene hunters (Janzen and Martin, 1983)? They probably survived in a peculiar habitat characterized by ample insolated ground yet sufficient rain for there to be large trees and sloppy seed predator rodents (or human fruit and seed harvesters), which offered sufficient seed dispersal. River edges, marsh edges, and the interface between tropical dry forest and desert are such habitats, and the aboriginal village/field edge adds a serendipitous fourth. The Spanish working horse (Figure 4) found the fruits abandoned by their extinguished ancestors and spread these two trees so thoroughly that today they are viewed by Mesoamerican societies as native and natural. And, in the case of *Enterolobium cyclocarpum*, cattle are surrogate horses (Janzen, 1982a).

However, as the motorbike and car replace the horse today, and as the cattle industry fades, these two trees are left as very visible living dead scattered across the former ranch lands, their abundant fruits rotting below the parent tree, the newly

Figure 3 A living dead *Crescentia alata* fruit crop presented to earthbound extinct megafauna (Figure 4). Sector Poco Sol, Area de Conservación Guanacaste, May 28, 1988.

Figure 4 An earthbound extinct megafauna returned from the Costa Rican Pleistocene by Spanish immigrants, breaking a *Crescentia alata* fruit (Figure 3) to eat the molasses and seeds inside. Sector Santa Rosa, Area de Conservación Guanacaste, 1980.

germinated seedlings killed by fungal pathogens nourished by the annually replenished seed crop, and the rare escaped seedling killed by herbicides, grass fires, and cosmetic cleansing.

When is a Tree not Living Dead?

Earlier I noted that if each member of a tree species were to abruptly fall over dead the moment that it ceases to be a reproductive member of its population in its ecosystem, there would be far stronger alarm cries across the tropics about extinction rates and realities.

However, the isolated tree, left an adult in the open as the forest is mined away from around it (Figure 2), is not necessarily or automatically a member of the living dead, or at least not necessarily at that moment. At least two circumstances may help to avoid this label. First, the pollinator community and the seed dispersal community for that tree may still be of a structure such that they confer sufficient amounts and patterns of their services and do so with the new reproductive phenology that will be expressed by the tree in its “new” habitat. And males do have fitness. A plant may never set a fruit or never have a surviving seedling from its seed crop, yet it still may be very much a member of the reproducing population (e.g., Aldrich and Hamrick, 1998). Plants contribute pollen “outward” as well as receive it from

unseen members of the population. There may be some circumstances where this or that member of the pollinator guild will in fact carry pollen from that isolated tree back into the forest. At least potentially this may remove the living dead label.

Second, the new pattern of seed/seedling/sapling safe sites for that species may be sufficient for population survival, even if different. A novel demography, reproductive phenology, and microgeographic structure will ecologically emerge, reflecting the serendipitous matching of the tree’s traits to these new conditions.

For the survivor, such ecological fitting (Janzen, 1985) of an individual (or a population) into the environment newly thrust upon it is the same process as occurs when a tree species is anthropogenically introduced to a new place. Whether introduced by humans or by natural processes, its survival there demonstrates that it has ecologically fit in. Such introduction may occur into a natural ecosystem or one variously anthropogenically perturbed. Sloppy deforestation may create many living dead, only mildly impact some other species, and favor yet new introductions into the region by having removed competitors or consumers.

A population of plants in a newly altered landscape is not necessarily at a given moment either “dead” or “alive.” Just as the relationships of an individual to its ecological circumstances may decay slowly, it is also easy to visualize a population being sufficiently anthropogenically impacted that it gradually decays over several decades-to-centuries-long generations. This state of decay is an intermediate between living dead and “normal surviving.” The portion of a population of trees at some geographic point may be in a constant state of swinging between being “okay” and living dead, as its associated climate and community of interactors goes through their own changes.

A species’ population in its totality may also be waxing or waning in geographic coverage, density, “living deadness,” or all three. Living dead are found at the geographic or demographic margins of all populations. It is just that human activity in ecosystem modification (elimination, simplification) simultaneously impacts so many species, and is so omnipresent, that it creates large numbers of living dead in the same place at the same time. These then carry the tragic perceptual load of tricking us into thinking that all is much more well than it actually is.

But ecological neutering, expressed as here in the terms “living dead” or “latent extinctions,” is not restricted to the circumstance of the single tree in the field or a single portion of a population. The living dead are an integral part of natural age-structured mortality. Any field biologist can identify a large number of young individuals—seeds, seedlings, saplings—that have a vanishingly small chance of survival as individuals. The forest understory is densely populated with them, as is each squirrel’s winter seed cache, as is the patch of seedlings below the healthy parent tree, as is the ground covered with epiphyte seeds that fell past the branches of the trees above, as is the floor of the cave littered with bat-dispersed seeds. A very large part of the world’s herbivore machine is run with this fuel and actually should be labeled “detritivore” rather than herbivore.

The implications for evolutionary biology are huge, given that no matter how much herbivory occurs on these living

dead, there can be no natural selection inflicted on the food populations.

Living dead adult individuals are also a prominent part of many undisturbed habitats and ecosystems. These are the waifs, the strays. Each of these is a plant whose seed arrived, grew to an adult, but found itself in a place lacking whatever is needed to maintain a viable population (Janzen, 1986c). In complex interwoven tropical habitats and ecosystems, the species list in a given place may contain as many as 10 to 20% of these kinds of living dead. For example, if a valley-bottom forest is eliminated, over time a significant number of tree species may disappear from the adjacent ridge, not because of any direct impact on the ridge forest but because the portions of the populations that were there are no longer maintained by seed flow into them from the valley bottom. This phenomenon is particularly visible where a particular soil or slope is thoroughly cleared for a crop, and the natural vegetation is left relatively intact in a neighboring habitat, ostensibly to protect it. Some species disappear because the conserved habitat did not really have its mutualist animals and physical climate conserved, or because it is too small, but others disappear simply because they were naturally occurring living dead.

Not to belabor the obvious, a tree standing dormant in the tropical dry season is not reproducing in the narrow sense, but it is also not necessarily living dead. But this is tricky for the observing human. We are very accustomed to being around trees that are not, at that moment, undergoing anything that appears to be reproduction, yet are members in good standing of quite surviving populations. The living dead tree does not display anything much different at first glance. Recognition of living dead status requires in-depth knowledge of its activities over decades, requires knowing if and where its pollen is going, and requires knowing where its seeds are moving to and what happens to them when they get there. This understanding is not acquired with the casual glance (e.g., Aldrich and Hamrick, 1998; Curran *et al.*, 1999; Hallwachs, 1986).

What of Small Plants?

The isolated tree in the pasture has been a convenient illustrative example, but the world to which these ideas apply is far greater than that of large tropical trees. A small herbaceous plant may be a perennial with longevity like that of a tree. When the euglossine bees are extinguished through forest partial clearing, a *Catasetum* orchid they pollinated is left high on the main trunk of a shade tree left behind, a living dead in its own right. The orchid may flower for a century, waiting in vain for its long-distance pollinators (Janzen, 1974). They are long gone, their year-round nectar and pollen sources turned to charcoal. A living dead clump of perennial grass on a landslide scar may for many decades produce its small hard seeds, designed millions of years ago for a trip through a seed-dispersing, now-extinguished, large herbivore to a new disturbed site (Janzen, 1984). It finally succumbs to its individual sterile fate as the landslide scar revegetates to forest. A living dead herbaceous morning glory (*Convolvulaceae*), sprouting and flowering year after year into the isolated roadside ditch from its underground tuber, may never again

see the bees that once moved among its flowers and the flowers of the many other forest-edge species that once sustained them (e.g., Frankie *et al.*, 1998).

But as mentioned earlier for a population of trees, even a population of annuals may also be a living dead population. Yes, each year it may flower and seed and disperse and then again germinate with the next rains. But did it make “enough” seeds? Were they set at the “right” time? Did they have the right genetic composition? Did they move to the right safe sites? Were those sites there to be moved to? Does the population do all this and much more to hold its place in the naturally shifting nature of its surroundings? Each year the population may decline a bit. Maybe even in some years it recovers. But overall, gradually it slides into local extinction.

Looking backward at the history of a plant population “going extinct,” it may be possible to describe the decay of such a living dead population. Looking forward, however, it is much harder to label than is the living dead tree in a cornfield. After all, all populations have their ups and downs. How to know, other than retroactively, when a down is a downswing versus a slide into extinction? When the habitat destruction is major and obvious, the prediction is much easier, but perhaps more scientifically trivial, than when the habitat destruction is piecemeal, fuzzy, or widespread yet light.

What of Animals, Those Things that Move?

Reproduction—that is, membership in the population—has two components. On the one hand, it is self-evident that the individual needs to be physiologically able to reproduce. On the other hand, if it is ecologically neutered, it is as dead as if sliced off with a chain saw. Selection has not generally favored the ability of a tree to “know” that it has been ecologically neutered by the removal of its pollinators, its dispersal agents, or the safe sites for its juveniles, and then take remedial action. What would the mutant tree have to be able to do? Walk back to the forest? Animals, with their chance to move to a new ecological circumstance, get horny. They search for nesting sites and mates, they may fight harder for their surviving fewer children, or they may migrate or emigrate to other places. But, in the face of the sweeping and omnipresent hand of humanity, busily extending its extended genome to cover the globe with both people and their domesticates (Janzen, 1998), where is the potentially living dead animal to go, and how long does it have to get there? One can search only so long before dying of old age, becoming a road kill, or running out of stored food reserves.

The tropical agroscape, and most wildlands as well, are awash with living dead animals, animal populations, and animal arrays (also known as “communities,” whatever those are). Latent extinction is everywhere, but it operates more rapidly on animals with their high turnover rate and their lower capacity for extended lives as dormant seeds, resprouting root stocks, clonal patches, and so on.

Humans contribute in a curious perceptual manner to us being less aware of the animal living dead. At the level of the large animals, “everybody knows” that jaguars and tapirs are still “here” because everyone knows someone who knows someone who saw one once. One sighting of one 10-year-old

jaguar crossing the road at noon 12 years ago will sustain the living dead jaguar in that area for decades, long past its consignment to the litter. It has taken more than three decades for the myth of Costa Rican giant anteaters, which once ranged these forests, to die a natural death.

Collectors and collections do their part as well. There is a snapshot of history present in our museum drawers, each specimen with its neat locality label. These collections continue the illusion of survival long past the reality. Retroactive data capture from museums gives a distribution map not of what is today on the Costa Rican countryside, but rather what once roamed where today sweeps unbroken waves of sugarcane, pasture, plantations, and horticulture. Intellectually every taxonomist knows this, but the orderly march of specimens across the museum drawers that read Panama, Costa Rica, Nicaragua, Guatemala, Veracruz, and San Louis Potosí lull one into thinking “surely over that huge geographic range there are still viable populations.” Plants are not immune to these processes. It is just that with the more illusive, the shorter lived, the more mobile, the animal living dead may be more easily manifest in historical collections than on looking out the car window at 70 kmph.

And, when one descends from a field vehicle somewhere, a rare butterfly flutters from the museum drawer and down the roadside ditch, the cruel illusion is reinforced. Highly mobile animals are particularly effective at hiding the living dead from perception. The last living dead Costa Rican green macaws will fly across the countryside for decades. One small viable population of butterflies can create hundreds of living dead individuals searching across the food-plant-free agroscape until dying on windshields, of pesticides, or in the collector’s net.

Some animals, like some plants, thrive in the agroscape. Are they living dead as well? The agroscape changes its biotic and its physical traits at the whim of some combination of the market and our technical ability to (re)engineer our domesticates (and produce new ones). Overnight the agroscape can flip from heaven to hell for a particular species. When cotton was the crop of choice on the Costa Rican countryside, the world was an ocean of food for native *Dysdercus* cotton-stainer bugs (as well as for a number of other native cotton herbivores). The local extinction of the bugs’ original wild food plants (Malvaceae, Sterculiaceae, Bombacaceae) that accompanied the forest clearing for cotton fields was invisible. But when the downstream shrimp industry decided that it could no longer tolerate the pesticide runoff from the cotton fields, and cotton went the way of history, then so did the populations of cotton stainers. Some remain on as tiny (living dead?) populations on the seeds of local roadside malvaceous and sterculiaceae herbs, but even these may be living dead with their food plants easing their slide into extinction.

Does the ecologically neutered tree try harder, as an animal might? Could there be selection for such behavior? What does the isolated tree in the field perceive? What is perceived by an elephant-dispersed tree in a forest where the elephants have been extinguished? The tree in the field can know that much less pollen of this or that genetic composition now arrives, and may adjust accordingly—it may flower longer, it may set more seeds that are fertilized with its own pollen. It may make more flowers more regularly or it may set more wood or grow a

larger crown. All of these things are simple responses to a circumstance that must occur in a natural forest to this or that individual that is not living dead. But the extinction of animal dispersal agents and safe sites for juvenile plants goes unheralded, with not even a potential feedback loop.

And What of the Things that Eat the Living Dead?

All have their predators, their parasites, their mutualists, their scavengers. Many of these are quite dependent on the traits of their hosts. Food is not food is not food. Narrowly host-specific specialists abound.

For every living dead individual, population, or species, there is a large suite of consumers—individuals, and even species—living at the margin of their existence. A seed predator weevil—*Rhinochenus stigma*—passes its larval stages in the pods of guapinol (*Hymenaea courbaril*) on the Costa Rican countryside (Janzen, 1974). It maintains what appears to be a healthy population in the annual to supra-annual fruit crops that are destined to fall and rot below the parent in the absence of both the Pleistocene megafauna and the agouti (*Dasyprocta punctata*), contemporary inheritor of the guapinol (Hallwachs, 1986). But as each of those old guapinol trees dies at the end of its 200 to 500 year life span, the weevil population takes another hit. One day the last living dead guapinol trees will die, and along with them will go what appears today to be a perfectly healthy community of weevils.

The guapinol is also fed on by leaf-eating caterpillars. One, a large saturniid, *Schausiella santarosensis*, eats only guapinol leaves and will go the way of the *Rhinochenus* weevil. Another, *Dirphia avia*, also a large saturniid, feeds also on the foliage of Spanish cedar (*Cedrela odorata*), mahogany (*Swietenia macrophylla*), oak (*Quercus oleoides*), and guarea (*Guarea excelsa*) (Janzen and Hallwachs, 2000). As the adult guapinol trees dwindle in number, how the *Dirphia avia* population will twist and change will depend in part on how many individuals of the other living dead remain. (You guess: How many Spanish cedar, mahogany and oak trees will be left standing by the Costa Rican roadside?) Perhaps *Guarea excelsa*, its wood of no commercial value, will be the only host plant left. Enough to sustain *Dirphia avia*? Who knows, but it certainly won’t be the same moth population that it was before.

The flowers of the living dead *Andira* trees were once a primary food source for tens of thousands of individuals of hundreds of species of bees; today they are visited by only a pale shadow of this bee community (Frankie *et al.*, 1998). But those old adult *Andira* continue to produce their massive flower crops and will do so for many decades to come. Its copious fruits, now largely from pollination by domestic honey bees, lie rotting below their parents in the absence of the masses of frugivorous bats that once dispersed them (Janzen *et al.*, 1976).

As noted earlier, the living dead are a “natural” part of any plant population. They are those individuals that have fallen where they have no chance of survival to reproduction. There are even living dead that have lived past their reproductive age. However, these living dead differ from the tree in the field in a very critical way for those who consume them. These living dead are being continually replenished by the natural

dispersal process. They do not herald an invisible walk to extinction for the consumer.

Are There Living Dead Habitats and Ecosystems?

Even when heavily agroindustrialized, the tropical agroscape often has patches of wildlands (**Figure 5**)—forests along rivers and ravines, broken topography, swamps and marshes, vegetation on bad soil, no-man's land between rival owners, woodlots, hunting preserves, industrial accidents, parks, and parklets. This remaining natural vegetation is a patchwork and a dot map, and it appears to be 1 to 20% of the original vegetation. And it gives one hope.

One says, "aha, there are remnants. There is wild biodiversity on the countryside, in the agroscape. There is hope outside of the reserves" (which are so hard to maintain and seem so expensive in national park status). This is a cruel illusion. Descend to one of these patchlets of forest, so green, so tree-filled. It is a biodiversity desert, lacking 50 to 99% of its original biodiversity that it had when it was once part of a forested landscape. As a package it is a vegetational living dead. Its species list is a mix of actual living dead and a few species that can maintain viable populations under these circumstances. Our major problem is that we visit these patches as tourists. We were not there in 1965 to see their earlier biodiversity, to compare it with its pale shadow in 1999 (but see [Frankie et al., 1998](#)).

Why are the survivors living dead, and what happened to those that have gone locally extinct? Part of them went when the area got so small that there were no longer circumstances for a viable population size. Part of them were explicitly mined or hunted. Part of them went when their mutualists, prey, and hosts went. Part of them went when the neighboring habitat, a habitat that spit seeds into the remaining forest and thereby maintained a population there, went to croplands. Part of them went when the seasons got drier, or wetter, or windier, or more fire-rich, or longer, or shorter, or, or, or.

Even those national parks that seem so secure are at major risk from this phenomenon. When the Southeast Asian dipterocarp trees fruit, the wild pigs come from everywhere and the collective seed crop of the preserved forest patch has no chance of satiating these seed predators (e.g., [Curran et al., 1999](#)). It may be better to surround a conserved wildland with wild animal-free rice fields than oceans of secondary succession subsidizing waves of animals that then turn the small old-growth forest into yet more secondary succession by defecating seeds all over it (e.g., [Janzen, 1983a](#)).

The bottom line is that the complex fabric woven from thousands of interacting species has been ripped to bits. Many of those that seem to have survived are living dead, or the serendipitous few that find this new impoverished habitat to their competitive liking. In short, these patches are only pseudo-remnants, not really smaller pieces of what once was. Even those ecosystems and habitats that have always existed as small units—a marsh, a landslide scar, a volcano top, a patch of serpentine soil—did not live in isolation. Rather, each was maintained by a complex ebb and flow of immigrants, waifs, and influences from the neighbors. When the neighboring natural system is turned to cropland, the integrity of the small

Figure 5 A living dead patch (left center) of natural vegetation, composed primarily of living dead individuals, among rice fields. There is essentially no gene flow between the patch and the secondary successional wildland in the foreground despite the thin connecting strip of riparian vegetation. Southwest of Liberia, Guanacaste Province, Costa Rica, December 14, 1999.

natural patch (e.g., **Figure 5**) is usually trashed almost as badly as if an army of chain saws had run through it. It just takes a bit longer for the living dead to live out their physiological lives.

These impoverished patches are especially deceptive for the bioilliterate. For those to whom a forest is just a batch of large woody plants, for those who cannot or will not read the differences between an advertising ditty and a complex poem, the agroscape with its living dead and pseudo-remnant natural vegetation appears to be not much different from a glade and forest mix in a national park. All seems to be well. But when humanity expects something from that wildland patch, it discovers that almost all of its tropical biodiversity is gone.

These patches have also played a mean trick on the conservation community. A huge portion of the world's conservation policy is based on the understandings of nature held largely intuitively by those who have grown up extra-tropical and learned their lessons from extra-tropical ecosystems. They easily adopt the mantra of trying to save the biodiversity remnants scattered across the agroscape. They are especially prone to do so in the face of the frustration of trying to save very large (and commercially juicy) blocks of intact vegetation. The forest-patchlet-dotted agroscape of Minnesota or Sweden still collectively contains easily more than 80% of the species that were there when the European colonists arrived. However, the same snapshot of a Costa Rican agroscape contains at best 5 to 20% of what once was. And the percent is still falling rapidly because a huge fraction of what remains today is living dead.

The more biodiverse and the more complex an ecosystem, the more likely that human perturbation will create anthropogenic living dead among the species with longer-lived individuals. This is because perturbations strip away mutualists and other biointeractors, leaving behind the physiologically functional individuals to live out their neutered life spans. The more biodiverse and the more complex, the more likely

any given individual is to be dependent on one or more of these interactants to remain a member of the population.

This tropical-to-extra-tropical comparison, derived by spending my life peering closely at both tropical and extra-tropical habitats is a major driver behind the conclusion that in the tropics a triage decision is needed. The living dead are writhing in lethal pain on the battlefield of the tropical agroscape. If we expend our scarce financial, political, and social resources on them instead of saving a few large coherent blocks of multi-ecosystem biophysical units, in the end we will live an even yet more impoverished biodiversity existence.

The future of real conservation in the tropics lies in by-and-large focusing our efforts on the survival of a relatively small number of very large and diverse biophysical units, each complicatedly integrated with local, national, and international societies (Janzen, 1998, 1999). Painful as it may be, resources spent on trying to save individual species and small habitat fragments scattered across the agroscape, often living dead, is bad conservation economics and creates an angry antagonistic *Homo sapiens*.

We have no option in the tropics but to recognize that conserved wildlands are and always will be islands in an ocean of agroscape. Our task is to get on with rendering them into the highest quality islands possible, and not be distracted by, nor lulled by, the living dead individuals and islandlets. Yes, if there remains but just one Rembrandt painting, we of course save it even if it is bullet-holed and faded. However, we must recognize it for what it is and not convince ourselves that by doing so we have preserved our knowledge of European history.

Restoration Biology

The living dead are largely a negative force in the algebra of conservation biology and conservation reality. However, in those few cases where ecosystem restoration is desired or serendipitous, their life span delimits a window of opportunity for the reintegration of their species into the restoring ecosystem. Reintegration is not an unqualified given, however. A single large tree in a pasture being restored to forest may be dropping its seeds and fruits into an early successional old-field community that for decades is still way too unattractive to contain the seed dispersal coterie that will begin to restore the demography of that tree species. Equally, the pollinators of its flowers may already be extinct, or abhor the young secondary succession coming up below the large old parent. And finally, the physical climate of the highly deciduous and dry-season blasted secondary succession may well be a dismal place for a seedling or sapling of that old-growth giant. As every plantation initiator knows, the act of stuffing seeds into the ground does not a plantation make.

Until a very short time ago, the California condor was made up of living dead individuals. They were brought into captivity (e.g., transplanted to a safe field), reproduced (e.g., seeds collected and grown in pots), and have been put back out, hopefully in an agroecosystem with a friendly sociology. This habitat is, however, very seriously impoverished through reduction of marine mammal populations that so kindly

generated the cadavers for lunch, and the California condor may always be dependent on human subsidy.

Many species of living dead may be rescued in this manner, if we care enough to spend the resources on them and gather information about them. But before racing out to apply the same technique to the living dead guapinol trees in the centers of Costa Rican pastures, a question very much needs to be addressed. Would not the same money spent on saving large blocks of guapinol-occupied wildlands, complete with their pollinators and dispersal agents, not generate vastly more conservation of guapinol and its hundreds of thousands of compatriot species? Yes, even these large blocks of wildland will contain some living dead. The wildland's biodiversity will attain an equilibrium density at whatever number of species survive the reduction from a continent of wildland to a large island of wildland. Those who are extinguished during this process will suggest the list of who were the living dead.

Loss of Biodiversity, Overview

Robert Barbault, Museum National d'Histoire Naturelle CNRS, Paris, France

© 2013 Elsevier Inc. All rights reserved.

Glossary

Biodiversity The variety of organisms considered at all levels, from genetic variants within the same species to the entire range of species and ecosystems.

Extinction The disappearance of any lineage of organisms, from populations to species and higher taxonomic categories (genera, families, phyla). It can be local or global (total).

Genetic drift The process of random sampling of genes that leads to changes in the genetic composition of a population. The effect of this process is particularly important in small population sizes.

Homozygous Possessing the same gene form (allele) on both chromosomes.

Locus The position on a chromosome of a gene. It is determined by any number of allelic forms.

Metapopulation The set of populations (or subpopulations) of the same species, linked by migration. It is characterized by the processes of local extinction and recolonization.

Pleistocene The geological time that ends with the last glacial period and the appearance of humans. It started 2 million years ago and finished 10,000 years ago with the end of the last Ice Age.

Stochastic The result of chance and random processes.

The extinction of a species, like the death of an individual, is a natural phenomenon – its inevitable destiny. In fact, during the long history of life, earth has undergone several periods of mass extinction. However, the crisis of current extinction differs from the preceding ones in that it is the direct result of human activities. Through our ecological success – have we not invaded the entire planet? – amplified by our industrial and technological revolutions, our species exerts such an impact on the biosphere that today, we are witnessing an acceleration of extinction phenomena without precedent. The objective of this article is to address the patterns, causes, and extent of such losses of biodiversity.

Lessons From The Past

The longest phase in the evolution of life on our planet extends for the 2 billion years from the appearance of the simplest molecules capable of autoreplication to the appearance of the first prokaryotes. Unfortunately, nothing is known about the evolution of biodiversity throughout this very long period, dominated by microorganisms. Our focus concerning extinction must therefore be restricted on two kingdoms, plants and animals, or in other words, on the past 600 million years (My).

Extinction Rates Deduced from the Fossil Record

Table 1 shows the estimates for the average life span of species in various groups of fossils from their origin to their disappearance. Overall, the average life span of the species is about 5–10 My.

Based on this estimate, and keeping in mind that the total interval of time considered is equal to 600 My, one can estimate that the present stock of animals and plants accounts for only approximately 1–2% of all species that have ever lived. However, this evaluation obviously depends on the quality of the fossil record. One should also note that the estimated life

spans vary considerably according to the groups considered (**Table 1**). In particular, according to Raup, the average duration of mammal species is on the order of 1 or 2 My, much lower than the 10 My estimated for (mainly marine) invertebrates. Taking into account this variability, it is estimated that the current species of plants and animals account for approximately 2–4% of those that have ever existed. Rates of extinction tend to vary considerably over time (**Figure 1**). Thus, four of the five major extinction periods in the fossil record (**Figure 1**) each eliminated between 65% and 85% of the marine animal species (Ordovician, Devonian, Triassic, and Cretaceous), and one (Permian) eliminated 95% or more.

Mass Extinctions Since the End of the Pleistocene

During the past 50,000 years, several extinction episodes have occurred almost exclusively among terrestrial mammals, some birds, and, to a lesser degree, some reptiles. A comparison of the data gathered on the various continents makes it possible to refine the explanatory assumptions (**Figure 2**). In Africa,

Table 1 Estimates of species' life spans in various groups from origination to extinction^a

Group	Species' average life span in millions of years
All invertebrates	11
Marine invertebrates	5–10
Marine animals	4–5
Mammals	1–2
Diatoms	8
Dinoflagellates	13
Planktonic Foraminifera	7
Bivalves	10
Echinoderms	6

^aBased on data from various sources.

Figure 1 Although the total number of families and species has increased over the eons, during each of five episodes of natural mass extinction a large percentage of these groups disappeared. We are now at the start of a sixth episode, the Pleistocene extinction, as human populations eliminate species through habitat loss and overharvesting. Reproduced from Primack RB (1993) *Essentials of Conservation Biology*. Sunderland: Sinauer Associates.

several genera of mammals had evolved and also become extinct throughout the Pleistocene up to the Holocene, 10,000 years ago, but a primarily intact fauna remained. In Europe, only the largest mammals became extinct (> 44 kg). A massive peak of extinctions occurred in Australia, with 86% of the large-bodied animal genera, including the large reptiles and giant birds, becoming extinct at the end of the Pleistocene. The majority of extinctions of the megafauna occurred about 30,000 years ago. Finally, in North America, mass extinction occurred between 10,000 and 12,000 years ago. Of the 37 kinds of mammals that became extinct, 33 weighed more than 44 kg. Similarly, extinctions in South America only affected the genera of animals exceeding 44 kg.

Two kinds of interpretations have been advanced to explain these extinctions, one focusing on human activities as driving extinction and the other focusing on climate changes. Thus, the episode of extinction in North America occurred at the end of the Pleistocene, when temperatures increased, leading to changes in the composition and the structure of plant communities, thus disturbing the interactions between plants and their browsers, and consequently leading to the extinction of many herbivores (particularly the large ones) as well as the predators that depended on them. Similar arguments may be used to

explain the extinctions that occurred in Australia, where the climatic change at the end of the Pleistocene was associated with a higher frequency of drought periods. However, the asynchrony of the extinction crises in America and Australia may lead one to lean more toward the role of humans, since the colonization of these continents by humans was also asynchronous.

The well-documented case of Madagascar is particularly interesting. Humans arrived in Madagascar 1500–2000 years ago. At the beginning of the Christian era, 17 species of lemurs inhabited the island. Seven of them disappeared about 1000 years ago; all but one were large species, probably diurnal and mostly terrestrial. The surviving species were, in contrast, either nocturnal or small, arboreal species. Three species of mammals from other families disappeared at about the same time: a pigmy hippopotamus, *Hippopotamus lemeriei*, and two large carnivores, *Cryptoprocta spelea* and *Plesiorycteropus madagascariensis*; furthermore, two species of the giant tortoises, *Geochelone*, and the elephant bird *Aepyornis* (which is, at a weight of 500 kg, the largest known bird), became extinct. While it is not clear whether these extinctions are caused by the direct effects of hunting or by a degradation of the environment, it is certain, however, that they are the result of human activities.

Figure 2 The extinction of large vertebrates coincided with the arrival of humans in Australia, North America, Madagascar, and New Zealand. In Africa, where humans and animals evolved together for millions of years, the damage was less severe. Reproduced from Wilson EO (1992) *The Diversity of Life*. London: Allen Lane, The Penguin Press.

Current Extinction Rates

In 2002, world leaders pledged, through the Convention on Biological Diversity ratified in 1992, to bring about a significant reduction in the rate of biodiversity loss by 2010. This so-called “International year of biodiversity” is gone and the rate of biodiversity loss does not appear to be decreasing (Butchart *et al.*, 2010). However, since the Earth Summit of Rio (June 1992), the scientific information about the current rates of extinction has been strengthened (Lawton and May, 1995; Millennium Ecosystem Assessment, 2005; Leadley *et al.*, 2010).

Recent and Current Extinction Rates

To measure the current erosion in biodiversity, biologists have estimated the current rates of extinction and then compared them with rates that would be expected in the absence of a crisis. The rate of extinction is the percentage of a given systematic group that disappears during a given interval of time. Based on paleontological archives, David Raup has estimated the average life span of animal species to be between 1 and 10 My, depending on the zoological group. Thus, an average life of 5 My per species is usually taken as the normal expectation.

To estimate the observed rates of extinction, biologists have calculated the percentage of all known species that have become extinct in the past 400 years (Smith *et al.*, 1993). However, these fractions largely underestimate the current rates of extinction, because the majority of species were identified only recently, during the nineteenth and twentieth centuries. Only vertebrates and plants were already well inventoried in the eighteenth century. Under these conditions, estimated rates of extinction for the period 1600–2000 are undervaluations of the number of species that have become extinct during the first three centuries of this period.

To avoid this pitfall, the percentage of known species that disappeared during the twentieth century is presented here (Table 2). These values represent good estimations for plants and vertebrates, but may still be underestimations for the other groups that were inventoried later because of the scarcity of specialists for the job. As we can see, the reliable values obtained for plants and vertebrate are very high, between 50 and 260 times higher than expected.

Thus, we are really facing a strong acceleration of extinction processes, justifying the title of Richard Leakey and Roger Lewin’s book: *The Sixth Extinction* (Leakey and Lewin, 1995).

Estimate of the Future Rates of Extinction from the Area–Species Richness Relationship

Future rates of extinction can be estimated by merging the estimates on the losses of the environment (e.g., deforestation) with the expected relationship between area and species richness. This relationship is an empirical rule, based on a number of studies, that connects the number of species S for a given taxonomic group (coleopterans, birds, vascular plants, etc.) and the area A of the islands (true islands, or ecologically isolated areas such as lakes, mountain peaks, and clearings in a forest) inhabited by the species (Figure 3). Generally, the relationship between species richness and the area has the following form:

$$\log(S) = c \log(A)^z$$

where c is a constant and the parameter z is usually between 0.15 and 0.35. Assuming that this equation can also describe the reduction of species richness driven by deforestation or other processes decreasing the area of suitable habitat, and taking into account the current rate of deforestation in the tropics (which varies between 0.8% and 2% per year), one can deduce an annual rate of extinction of between 0.2% and 0.5%. In other words, with a total richness of currently 5 million species inhabiting the planet (our minimal estimate), between 10,000 and 25,000 species will disappear every year.

However, this kind of extrapolation is associated with several problems. It is not known, for example, up to what point the effects of the fragmentation of the environment, particularly in the tropics, can be deduced from the area–species relationship that has been described mainly for insular biogeography. Thus, Simberloff stressed that, during the past two centuries, only three species of birds are known to have become extinct in the forests in the eastern United States, even though the forest has been reduced to small fragments with a total of only 1–2% of their original area.

Table 2 Estimated rates of extinction in the twentieth century

	Number of species described	Extinctions in the twentieth century		Extinction rate for the twentieth century	Endangered species
		Expected	Observed	%	
Plants	270,000	5.4	270	0.1	30,000
Vertebrates	50,000	1	260	0.6	2300
Molluscs	70,000	1.4	(140) ^a	(0.2)	920
Insects	950,000	19	(50)	(0.005)	537
Crustaceans	40,000	0.8	(5)	(0.02)	407

^aLikely underestimated.Source: Reproduced from Teyss  re in Barbault R and Chevassus-au-Louis B (2004) *Biodiversity and Global Change*. Paris: Minist  re des affaires   trang  res-adpf.**Figure 3** An example of the log–log relationship between the number of breeding-bird species (S) and the area of Islands and continental regions in the Mediterranean (A). Reproduced from Blondel (1995).

Despite such uncertainties regarding our estimates, it is certain that the reduction and the fragmentation of the environment, even if not always resulting in a reduced density of populations, will increase the risk of their becoming extinct. See **Box 1**.

Mechanisms of Extinction

What aspects of the environmental conditions make a species or population become extinct? It is clear that, if the mortality rate continuously exceeds the birth rate, a species will eventually become extinct. However, any prediction (which is based on perhaps a decade of observation) about extinction during the next, say, 3000 or 7000 years assumes that nothing will change. Since we are assuming that the major cause of extinction may be humans, this assumption appears unlikely.

Therefore, we will discuss more short-term risks of extinction, those associated with an environment in which, in principle, the population should persist (where births exceed deaths, at least at low population densities). In doing so, we will distinguish isolated populations (a situation that is rapidly developing with the human transformation of landscapes

due to human activities) and interconnected populations constituting so-called metapopulations. The main difference between the two is that (unless due to human intervention) only interconnected populations can benefit from immigration.

Isolated Populations

Low Population Densities: The Allee Effect

At low densities, individuals may be distributed over distances that are much larger than those they usually move in, so that the probability of meeting one another for mating is small. Therefore, the growth rate of the population may decline below unity when the density is below a certain threshold. A well-established example of such an Allee effect leading to extinction is the mottled woodpecker *Dendrocopos medius* in Sweden in 1982. It is likely that an Allee effect is also responsible for the extinction of the migrating pigeon of North America, formerly so spectacularly abundant.

The possibility of extinction due to low population densities is particularly alarming for large animals, which live naturally at a low density, and for species with marked sociality.

Box 1 Future extinction rates deduced from IUCN Red Lists

The International Union for the Conservation of Nature (IUCN) proposed a number of criteria to classify the level of threats imposed on plant and animal species. Seven categories are defined:

Extinct: A taxon that has not been observed in nature for more than 50 years.

Endangered: A taxon close to extinction and whose survival is at risk if no action is taken to eliminate the causes of its disappearance. Included in this category are species whose populations are reduced to a critical level or whose habitats are threatened.

Vulnerable: A taxon at risk of entering the endangered class if detrimental factors continue to exert their effects. This category includes those taxons whose populations decrease as a consequence of overexploitation, large-scale habitat destruction, or any other perturbation of their environment, and those taxons whose populations remain abundant but that are nonetheless threatened by a variety of detrimental factors.

Rare: Taxa whose populations are globally rare even though they are not endangered or vulnerable. Such taxons are generally found in very specific areas or habitats or have widely dispersed small populations.

Indetermined: A taxon that has to be included in one of the above categories, but about which insufficient information is available to assess the level of risk.

Insufficiently known: A taxon thought to belong to one of the preceding categories, but without data to substantiate this.

Threatened: A taxon included in any of the preceding categories.

On this basis it appears (Vié *et al.*, 2009 and November 2009, IUCN synthesis) that from the census of greater than 47,677 species censused in the world, 875 were extinct (809 totally extinct and 66 extinct in the wild) and 17,291 were threatened. The estimates are particularly sound for vertebrates. In the case of the 5490 species of mammals for instance, 79 were extinct, 449 endangered, and 505 vulnerable. However, things are becoming worst particularly for amphibians (30% threatened over 6285 species) and freshwater fishes (37% over 3120 species studied).

Demographic Stochasticity

Changes in population density due to births and deaths necessarily imply the role of chance, as birth and death, but also the sex of the offspring and other parameters are random processes. It follows that there is a positive probability that all of the individuals in a population may die during the same time interval. This probability depends mainly on the population density – the ones with the lowest density being the most vulnerable – and on the mean and variance of the survival rate.

Environmental Stochasticity

In natural populations, the probability of having offspring or of dying is influenced by the environment, and these environmental effects have some degree of correlation among individuals. If the correlation is low, a failure, say, of one individual to produce offspring, may be canceled out, at the level of the population, by a large number of offspring produced by another individual. If, however, the correlation is high, the stochasticity will reduce the variance of the demographic parameters among individuals and therefore increase the risk of extinction. In the extreme, during a total catastrophe the correlation is complete, and all of the individuals die at the same time. Thus, high population densities are by no means a guarantee of population survival.

More formally, environmental stochasticity is evident in the temporal fluctuations of the growth rates of the populations. The increase in the variance of population growth increases the risk of extinction, in particular when the mean growth rate is low, the population density is low, or the carrying capacity of the environment is low.

Genetic Factors

Two widely discussed genetic factors associated with extinction, both of which are important in small populations, are inbreeding depression and the loss of evolutionary adaptability to new environments.

If a population goes through the bottleneck of a low population size, individuals are constrained to mate with close relatives. This is often associated with reduced viability or fertility, a phenomenon called inbreeding depression. The mechanisms leading to inbreeding depression are unknown for the majority of the species. In *Drosophila*, about half of the effect is due to the increased number of homozygous loci carrying recessive detrimental alleles (up to 5000); the other half is due to the accumulation of slightly deleterious and recessive mutations. Inbreeding depression has been established in many domestic species and zoo populations, but unfortunately, information is rare for natural populations.

The Critical Role of Population Size

The central message that emerges from most empirical and theoretical studies on extinction is that extinction risk increases, and thus the life expectancy of the population decreases, as population size decreases (Figure 4). Demographic stochasticity considerably increases the extinction risk if population size decreases below about 50 individuals; inbreeding depression is likely to become significant only under circumstances when a previously abundant population goes through a population bottleneck.

Metapopulations: Sets of Several Local Populations

Considering a metapopulation introduces an additional dimension to the risk of extinction, due to the possibility of dispersal from one local population to another. Seeds, spores, or animals may disperse passively or actively from their natal population over the landscape. If they arrive at a favorable site that is not already occupied by members of their species, they may be able to establish a new local population. In the long run, populations of a species may thus be established and disappear repeatedly at the local scale, while at the level of the landscape, one observes the dynamic equilibrium of a species moving among local habitats.

Figure 4 Extinction vortices: the smaller a population becomes, the more vulnerable it is to demographic, genetic, and environmental factors that tend to reduce population size even more and drive the population to extinction. Reproduced from Primack (1993) *Essentials of Conservation Biology*. Sunderland: Sinauer Associates.

The persistence of a metapopulation depends on processes that affect the rates of extinction of local populations, and also on processes that affect the establishment of new local populations. Two conditions must be fulfilled for the establishment of a new population: favorable sites must exist and a sufficient number of individuals must migrate from existing sites to the unoccupied habitats. This makes immigration and dispersal processes important mechanisms for the survival of metapopulations.

The survival of a metapopulation is threatened by two types of stochasticity, which are analogous to the demographic and environmental stochasticities involved in the dynamics of local populations: (1) the stochasticity of local colonization and extinction rates and (2) the regional stochasticity. The first involves the stochastic processes discussed earlier; the second, analogous to environmental stochasticity in isolated populations, applies if stochasticity has effects that are correlated among several local populations within the metapopulation. Since a significant source of environmental stochasticity is related to weather conditions, which are typically strongly correlated over a large spatial scale, one may generally expect a high degree of correlated regional stochasticity in metapopulations and thus high risks of extinction.

Causes of the Loss of Species and Genes

We have argued as if there were no change in the environment experienced by the populations, but there is, of course, hardly any doubt that the current increase in the rates of extinction is

primarily caused by drastic changes in the environment. This affects all of the key parameters associated with the risk of extinction: population sizes, the carrying capacity of the environment, the mean and variance of growth rates, the genetic structure of a population, the number and area of suitable habitats, and the number of local habitats forming a metapopulation. From this perspective, we will now consider four types of environmental changes that may initiate the extinction process: the destruction of natural habitats, over-exploitation by humans, changes concerning other species, and climate change.

Destruction and Changes of Natural Habitats

All animal and plant populations are adapted to the local conditions of their environment; their persistence depends on the maintenance of these conditions. Large climatic changes of the past, the periods of glaciation, for example, led to local extinctions and a shift of species' geographic ranges. These kinds of changes, however, were very slow, being spread out over periods of millions of years, so that most species were able to gradually adapt to or alter their geographic range according to the novel conditions. Humans introduced a novel dimension to the changes of natural habitats; human activities are more similar to volcanic eruptions than to gradual climatic change and thus could amplify its effects. At the time of the past glaciation, for example, the extinctions of the large mammals during the Pleistocene was partly because of human activities.

The main effects of humans on the environment are as follows:

1. Destruction of habitats (clearing forests, drying lakes, and humid areas, etc.).
2. Degradation of natural habitats (pollution, dams, etc.).
3. Fragmentation of habitats.

Destruction of Habitats

The most severe threat imposed on biological diversity is the loss of suitable habitat – and reducing habitat loss is the most important way of preserving the environment.

Loss of habitat has been the main source of extinction, at least in the recent extinctions of vertebrates. In many areas of the world, particularly on the islands and places where human populations are high, a large portion of the natural habitats has already been destroyed. Thus, in tropical countries, the destruction of the habitat ranges from 29% (Zambia) to 89% (Gambia) in Africa and from 41% (Malaysia) to 97% (Hong Kong) in Asia, and in most countries the number is above 70%.

Fragmentation of Habitats

The fragmentation of habitats is a process by which a large area consisting of a given type of environment is reduced in size and is divided into two or more fragments. These fragments of the original environment are often isolated from one another by a highly modified and degraded landscape. For example, the large stands of vegetation that used to cover vast areas of the world have increasingly divided into separated fragments. Europe as well as densely populated areas of Asia has experienced this process for centuries.

Such isolated fragments differ from the original environment in two critical ways:

1. The ratio of edge to area is increased.
2. The center of each fragment is closer to the edge.

Fragmentation of the habitat threatens the persistence of the species associated with it in various ways.

First, fragmentation may limit the capability of a species to migrate to, and thus to colonize, other habitats, because the landscape between the fragments creates an effective barrier to dispersal. In an undisturbed habitat, individuals can disperse over the entire landscape, which can lead to a stable metapopulation despite local extinctions (discussed earlier). If, however, the habitat is fragmented, the potential for dispersal and for colonization is often reduced. Thus, many birds or mammals, and many insects, are reluctant to leave the cover of their forest habitat and to cross small open spaces, as, if they do, they may be killed by predators prowling forest edges. Cultivated fields, measuring only 100 m in width, can constitute an insurmountable barrier to numerous invertebrate species. If the dispersal ability of, say, some mammals is reduced, plants might also suffer, as they may rely on these species for the dispersal of their seeds. Therefore, isolated fragments of habitat may develop that, although in principle may be suitable for colonization, cannot be reached by dispersing species; they will therefore remain uninhabited.

As some species disappear from a fragmented landscape as a result of natural processes in a metapopulation, while others

do not succeed in recolonizing the habitat, the number of species will decline over time. It must be noted here that, worldwide, most natural parks and reserves are too small and too isolated to harbor a large number of species; almost half of the protected sites have an area of less than 100 km² and 98% have an area less than 10,000 km².

By splitting a large and contiguous population into sub-populations restrained to limited areas, the fragmentation of the environment can precipitate the decline of species and their extinction. As we have seen, small populations are indeed more vulnerable to inbreeding depression, genetic drift, and several other problems. While a large contiguous area may support a single large population, it may well be that none of the fragments can harbor a population large enough to ensure its long-time persistence.

Second, the increased proportion of habitat edges in fragmented environments brings with it changes in microclimate – light, temperature, humidity, wind – but also increased risk of fire and higher vulnerability to novel species of predators and competitors (e.g. invasion of weedy species from disturbed environments; see **Box 2**).

Persecution and Exploitation of Populations

The persecution and exploitation of natural populations generally threatens a certain number of species with extinction, in particular the large-bodied ones. These, and in particular the vertebrates, are also those that attract most attention from the general public, protection agencies, and the scientific community. This is reflected in the considerable amount of scientific literature focusing on rational and controlled exploitation of natural populations, be it hunting or fishing.

It is generally known that large animals require larger reserves than small ones, due to their low population densities. However, although it is generally true that large animals have small population densities, this may be due in many cases to the past persecution or exploitation of these species. It must be emphasized that large-bodied species may survive in disturbed habitats, if they are not persecuted. Thus, in Finland, large birds and mammals, including predatory species, have become more abundant recently in a range of manmade landscapes, most likely because they are now protected.

Changes in the Biotic Environment

A common cause of extinction is the interaction with exotic species that had either been introduced by humans or had arrived naturally (**Box 3**). The introduction of exotic species threatens in particular small isolated islands with specialized endemic species. Large islands, however, are not protected from this effect: After being introduced to Australia, the red fox was responsible for the extinction of several small marsupials.

The isolation of insular habitats favors the evolution of endemic species, but it also makes them particularly vulnerable to invading exotic species. Only a limited number of species can reach islands; plants, birds, and invertebrates are the most common colonizers. However, insular communities generally have few or no predators and browsers (due to the

Box 2 Catastrophic extinctions following deforestation

The looming mass extinction of biodiversity in the tropical forests is a major concern for the future (MEA, 2005). It is reported here in two enlightening studies supported by broad-based empirical data.

An Amazonian Experiment

The Biological Dynamics of Forest Fragments Project (BDFFP) was initiated in 1979 as a large-scale experiment to assess the effects of fragmentation on Amazonian taxa. Standardized abundance data were collected for trees, birds, amphibians, mammals, and various invertebrate groups prior to experimental isolation of forest fragments of 1, 10, 100, and 1000 ha. These fragments were surveyed 22 years later (Laurance *et al.*, 2002).

The BDFFP results suggest that fragmentation alters population and community dynamics. As expected, they show that species richness is positively correlated with fragment size and that intact forest contains more species per unit area than fragments. Many large mammals, primates, and understory birds, but also some termite, ant, and butterfly species have disappeared from even the largest (100–1000 ha) fragments in the study area. Once isolated, small (1–10 ha) fragments initially lose species at a high rate. For example, dung and carrion beetle assemblages were markedly altered only 2–6 years after isolation. Local extinctions of birds, primates, and butterflies have also occurred more rapidly in small than in large fragments. In contrast, a few taxa like rainforest frogs have remained stable after fragment isolation. Moreover, the BDFFP researchers revealed the remarkable diversity of edge effects in fragmented forest and the importance of matrix effects.

Extinctions in Singapore

Since the arrival of the British in Singapore (a 618 km² island) in 1819, some 95% of the 540 km² forest was logged. From a census of 3996 species (and those known to have been present around 1819) by Brook *et al.* (2003), 881 were locally extinct 183 years later. Substantial rates of extinctions were found, especially for forest specialists (33%), with the greatest proportion of extinct taxa (34–87%) in butterflies, fish, birds, and mammals. Observed extinctions were fewer for species that prefer or tolerate open and forest-edge habitats (7%) like most amphibians and reptiles.

In conclusion, both experiments show (1) the extent and quickness of extinctions following deforestation; (2) the importance of matrix quality and edge effects for species survival; and (3) the diversity of responses exhibited by different taxa.

Box 3 Examples of extinction cascades due to introduced species

What happened to Guam's avifauna is a good example of the destructive effects of introduced species. Guam is an island belonging to the Marianes Archipelago, situated between Japan and New Guinea. Eighteen species of indigenous birds were known to inhabit the island, as well as seven introduced ones. Then, during the past 20 years, populations declined spectacularly: Today, seven species are considered to be extinct and four others have become so rare that their survival is endangered. Nevertheless, on other islands of the same archipelago, no comparable decline has been observed. Strikingly, the 10 forest species were all affected and in a similar manner: The birds disappeared first from the southerly forests during the 1960s, and then their decline spread progressively toward the north of the island. This decline coincided exactly with the introduction and subsequent spatial expansion of a tree snake, *Boiga irregularis*. Since this snake is absent on neighboring islands, there is good evidence that it was the cause of the observed declines and extinctions. Because of its arboreal and nocturnal habits, this snake is a voracious predator of perching birds and birds sitting on their nests, as well as of eggs and nestlings. Moreover, because it also predated on small mammals and lizards (the latter particularly abundant), it can attain high densities even while exterminating its most vulnerable prey species.

On Santa Catalina, an island close to California, 48 native plant species have been eliminated mainly as a consequence of overgrazing by goats and other introduced mammals.

At Madagascar, where the ichthyofauna is highly endemic, with 14 out of 25 genera unknown elsewhere, a recent inventory of freshwater environments was not able to retrace more than five. Introduced fishes dominate all aquatic environments. The combination of habitat degradation and the introduction of exotic fish seem to be leading the original ichthyofauna toward extinction.

The same has been found in continental aquatic environments, which, for aquatic species, are a kind of island surrounded by inhospitable terrestrial space. Originally, Lake Victoria had more than 350 endemic fish species. Today, many are rare or have become extinct after the introduction of the Nile perch, *Lates nilotica*, in 1960. In fact, the phenomenon is more complicated than that: In 1978, the perch did not yet represent more than 2% of the annual catch; in 1986, it represented 80%. Factors other than predation have played a role (algal blooms creating anaerobic conditions as a consequence of pollution by fertilizers and other pollutants).

difficulties of colonizing the island or of establishing a population on an insufficient area), and indeed, the species representing the highest trophic levels (e.g., the carnivorous mammals) may be missing completely. Since many endemic species on islands have thus evolved in the absence of the selective pressures of predators and mammalian browsers, they have not evolved (or have lost) any means of defense: Birds have lost the ability to fly and lay their nests on open ground and plants do not produce any chemical substances and do not have any protective tissues (spines) that could deter browsers.

Therefore, endemic species that can spread in the absence of these selective pressures may become extinct rapidly when the pressures appear: animals introduced into the islands eliminate them by predation or overgrazing. The introduced plants, however, equipped with a protected or a toxic foliage, have previously evolved to withstand browsing, so that they outcompete the endemic plants, enhancing the selective pressure by the introduced browsers and thus accelerating the extinction of the endemic species.

Moreover, insular species usually do not have an immune defense against foreign diseases; once introduced with the

invading animals, these can spread epidemically and can destroy the native populations. It is thought, for example, that the almost complete destruction of the Hawaiian avifauna – since 1850, 85% of the endemic species have become extinct or have been reduced to very small populations – is due to the spread of variola and bird malaria, introduced together with the mosquito *Culex quinquefasciatus* in 1826.

Extinctions caused by human activities in insular communities are much more frequent than generally recognized. Thus, the rate of extinction on the order of 1% given earlier is a gross underestimate of the true value. Current estimates indicate that 25% of endemic bird species have disappeared from islands as a result of human activities. There are, for example, only three species of winged rails today, while thousands have existed during the past 2000 years. We are justifiably worried by the current wave of mass extinctions threatening the tropical forests, but should also recognize that the oceanic islands have already undergone such mass extinctions.

Climate Change

Climate change over the past decades has produced shifts in the distributions and abundances of many species (Lovejoy and Hannah, 2005; Möller *et al.*, 2004). In some cases, it has been implicated in species extinctions (Box 4). Thus, using projections of species distributions for various climate scenarios, extinction risks for sample regions covering 20% of the Earth's terrestrial surface have been estimated by an international team led by Thomas *et al.* (2004). Exploring various approaches in which the estimated probability of extinction shows a power-law relationship with geographical range size, they predict, on the basis of midrange climate-warming

scenarios (1.8–2.0 °C, which looks very optimistic!) for 2050, that 15–37% of species in their sample of regions (Europe, Mexico, South Africa, and Queensland) and taxa (terrestrial vertebrates, butterflies and some other invertebrates, and plants) will be committed to extinction. The results of this kind of scenario depend on various hypotheses, such as the different levels of dispersal abilities of the species (Thomas *et al.*, 2004).

In the case of marine species, the impact of climate change is not limited to the effects of warming: there is also a direct effect of the increase of CO₂ in the atmosphere through ocean acidification. It appears as a pervasive stressor that could affect marine organisms and cause profound ecological shifts that may facilitate species extinction (Krocker *et al.*, 2010). Calcifying organisms such as crustaceans or corals are particularly sensitive to such acidification (see Box 5).

Ecological Reflection on the Primary Causes of the Current Crisis of Extinction

All organisms modify their environment, and humans are no exception. Thus, in a strategic document, jointly published by the World Resources Institute (WRI), the World Conservation Union (IUCN), and the United Nations Environmental Programme (UNEP), six fundamental causes for the impoverishment of biodiversity are recognized:

1. The rapid and unsustainable growth of human populations and the consumption of natural resources.
2. The continued reduction of the range of products in agriculture, forestry, and fishing.
3. The economic and political systems that do not take into account the environment and its resources.

Box 4 A mass extinction associated with pathogen outbreaks tied to global warming

As the Earth is becoming warmer, many species are likely to disappear, often because of changing disease dynamics (Pounds *et al.*, 2006). For instance, it appears that a recent mass extinction in amphibians is associated with pathogen outbreaks tied to global warming. During the 1990s, in the mountains of Costa Rica, the Monteverde harlequin frog (*Atelopus* sp.) disappeared along with the golden toad (*Bufo perigrinus*). An estimated 67% of the 110 or so species of *Atelopus*, which are endemic to the American tropics, have met the same fate, and a pathogenic chytrid waterborne fungus, *Batrachochytrium dendrobatidis* is implicated.

Chytridiomycosis is an infectious disease that affects amphibians worldwide. It is capable of causing sporadic deaths in some species and 100% mortality in others. For instance, mass die-offs in populations of the midwife toad *Alytes obstetricans* at high altitude in the western Pyrenees in both France and Spain were observed as early as 2002 and are spreading (<http://www.bd-maps.eu>; <http://www.sosanfibios.org>).

Box 5 Marine species face an elevated risk of extinction from global changes

Marine ecosystems are centrally important to the ecology of the planet: covering 71% of the Earth's surface, the ocean nurtured life on our planet and continues to play a dominant role in regulating the climate. Recent studies indicate that rapidly increasing greenhouse gas concentrations are causing a decrease in ocean productivity, altered food web dynamics, shifting species distributions, and elevated risk of extinction in many species (Hoegh-Guldberg and Bruno, 2010). Let us focus here on the case of coral species.

Coral reefs harbor the highest concentration of marine biodiversity and are facing increasing threats at local and global scales. In particular, rapid buildup of carbon dioxide in the atmosphere is leading to both rising sea surface temperatures and water acidification. The conservation status of 704 reef-building coral species was assessed using Red List criteria and measures of population reduction over time. One-third of these are in categories with an elevated risk of extinction. Declines in abundance are associated with bleaching and diseases driven by elevated sea surface temperatures, with the risk of extinction further exacerbated by local-scale anthropogenic disturbances.

A recent investigation of 328 colonies of massive *Porites* corals from 69 reefs of the Great Barrier Reef in Australia shows that calcification has declined by 14.2% since 1990. The data suggest that such a severe and sudden decline in calcification is unprecedented in at least the past 400 years. It could be a response to the declining pH of the upper seawater layers due to the absorption of increasing atmospheric CO₂ (De'ath *et al.*, 2009).

Table 3 Recent rates of conversion of natural habitat to specialized agriculture (the 10-year rate, up to 1987)

<i>Conversions to cropland (%)</i>		<i>Conversions to pastureland (%)</i>	
Paraguay	71.2	Ecuador	61.5
Niger	32.0	Costa Rica	34.1
Mongolia	31.9	Thailand	32.1
Brazil	22.7	Philippines	26.2
Ivory Coast	22.4	Paraguay	26.0
Uganda	21.4	Viet Nam	14.0
Thailand	17.1	Nicaragua	11.8

World Resources Institute and International Institute for Environment and Development.

4. The inequalities in the possession, management, and sharing of the advantages related to the use and the conservation of biological resources.
5. The legislative and institutional systems that favor unsustainable exploitation of resources.
6. The lack of knowledge and its applications.

In fact, the decline in diversity results from specific choices during the course of human development (Swanson, 1997). It is clear that, with population growth, demographic changes, and the associated technological development, humans are using an increasing share of the planetary resources. Indeed, it consumes, diverts, or holds approximately 39% of plant productivity, the fundamental source of energy for most living systems (Vitousek *et al.*, 1986). The rate of conversion from natural environments into agricultural systems, high in the developing countries (Table 3), remains a major threat for biodiversity. This is alarming not only for the future of many animal and plant species but also for humans.

In addition to the dangerous reduction of renewable resources from the environment, population growth leads to increases in pollution (including the gases responsible for the greenhouse effect), which threaten the balance of ecosystems and the climate. Novel models of development are necessary so that population growth does not exceed the carrying capacity of the planet.

The five other primary causes blame either our economic behaviors or the legal uses of the human societies. For thousands of years, the humans formed a mosaic of relatively autonomous areas. The state of knowledge, strategies of subsistence, and social structures evolved more or less independently in each area. What the populations required of the environment seldom exceeded the capacity of nature.

With the globalization of the economy, starting at the end of the past century, uniformity and interdependence have increased. In agriculture, for example, a small number of cultivated plants have come to dominate the global economy (Box 5). In fact, today, human societies mainly depend on four species of plants (maize, wheat, potato, and rice) for their basic needs. Furthermore, these species are used in the form of a decreasing number of high-output varieties. Thus, in Sri Lanka, the 2000 varieties of rice used in 1959 has decreased to 5 main varieties today; in India, 10 varieties out of originally 30,000 represent 75% of production; and about 62% of the varieties in Bangladesh and 74% in Indonesia are estimated to be derived from a single maternal plant (Box 5).

The process of conversion, which consists of investing capital in a type of resource that is economically advantageous,

is the principal economical force threatening biodiversity: Development and conversion go hand in hand, and conversion is the process by which habitat and its resident species are lost (Swanson, 1997).

The reduction in the number of cultivated species is accompanied by the disappearance of nitrogen-fixing bacteria, mycorrhiza, predators, pollinators, and many other species that have coevolved during centuries with the traditional systems of agriculture. The use of manure, pesticides, and high-output varieties accelerated this erosion.

Similarly, with regard to marine ecosystems, the vast world markets favored the development of blind fishing with, for example, gigantic drifting nets that trap not only enormous quantities of target species, but also a considerable number of other species of fish, mammals, and birds.

In addition, several factors led to an underestimate of the use of environmental resources. First, many resources are directly consumed without appearing on the markets. Second, the benefits of biodiversity are largely public goods. For example, while the protection of wetlands may benefit a population, the benefit is so diffuse that traditional economic theory cannot incorporate mechanisms that would preserve them. Correctly evaluated, the natural systems and their biodiversity are major economic assets. However, as these systems are often underestimated, economic theory considers the conservation of the biodiversity an expenditure rather than an investment.

In response to this challenge, a new discipline is being developed that integrates economics, ecology, and public policy: ecological economics. As Timothy Swanson emphasized, diversity decline is a specific form of institutional failure: the failure to create institutions that internalize the values of biodiversity within the decision-making of states and individuals making conversion decisions.

The reduction in the number of the species and the destruction of habitats are the standard in many countries where a minority of the population controls most of the territory. The rapid profits gained from excessive logging or fishing go to a minority, while the local population, which depends on the sustainable production of the resources, pays the price. In fact, the ownership is often more likely to be granted to those who cut down and colonize forests and other areas covered with natural vegetation than to the inhabitants of the forests living on the sustainable harvest of the natural products. Any uncertainty in the ownership dissuades good management practices and encourages overexploitation.

A second problem stems from the concentration of the control of the resources and the responsibilities for decisions

about environmental policy in the hands of citizens. However, in many societies, it is the women who manage the environment and understand the value of the biodiversity for agriculture and health.

A third problem is that of international trade, the debt, and the policies of technology transfer that support the inequalities and often reinforce the imbalances observed within nations. To preserve biodiversity, the industrialized countries must reverse this flow. If the developing countries continue to be excluded from the markets, to be deprived of access to technologies, and to be blocked by their debts, they will have neither the means nor the incentives necessary to preserve their biological resources.

Glossary

Extinction spasm or pulse A catastrophic burst of extinctions, peaking in less than a millennium.

First contact Initial human arrival on a landmass followed by human colonization.

Late Quaternary extinction event Selective prehistoric extinctions, typically catastrophic, eliminating within the past 40,000 years two-thirds or more of large land mammals of America, Australia, and Madagascar and at least half the species of land birds on remote islands of the Pacific. Humans are present or suspected to be present in virtually all cases.

Megafauna Large terrestrial vertebrates variously defined as > 1, > 10, and > 44 kg adult body weight. Equivalent to 100 pounds and similar to the average weight of adult humans, a body size exceeding 44 kg is easily visualized and is adopted here.

Quaternary The ice age of at least the past 1.81 million years, including the Pleistocene and the Holocene, the latter representing the past 10,000 years.

Radiocarbon dating An isotopic or nuclear decay method for inferring age of organic materials. Carbon 14 is produced in the upper atmosphere by cosmic ray bombardment and oxidized to form $C^{14}O_2$. Distributed through the earth's atmosphere and oceans, a small percentage is incorporated into a variety of organic materials to decay with a half-life of 5700 years. By dating tree rings of known age, and other methods, radiocarbon determinations can be calibrated. Although routine application of radiocarbon dating is usually limited to dates of less than 40,000 years, ages up to 75,000 years have been measured.

Introduction: Prehistoric Extinctions

The late Quaternary extinction event (LQEE) is best known by the loss of large mammals (megafauna) from certain continents. Familiar faunal examples of the LQEE include woolly mammoths of the Northern Hemisphere, woolly rhinos in northern Eurasia, ground sloths and glyptodonts in the Americas, and diprotodonts and giant kangaroos in Australia. Comparisons between landmasses are revealing. The continents differ significantly in both the magnitude and in the timing of their extinctions. First Australia, then North and South America, and lastly Madagascar (the Island Continent) rapidly lost two-thirds or more of their large mammals (Figure 1). In contrast, losses were comparatively gradual and much less severe in Eurasia and Africa. Although small animals of the continents seldom suffered extinctions, thousands of endemic mammals, birds, and reptiles vanished from oceanic islands.

At least 85 genera of large (> 44 kg) mammals, half of the terrestrial megafauna of the planet, disappeared from the continents in the past 100,000 years. Now "out of sight, out of mind," the extinct mammoths and other large animals of the Quaternary coevolved with modern plant species, thereby shaping certain features of vascular plant anatomy and biochemistry. Undoubtedly, the extinct species were just as influential as living megaherbivores in determining the structure of natural communities (Owen-Smith, 1988). Before 13,000 years ago the diversity of large mammals in the New World would have resembled that currently found in African or Asian game parks. Megafaunal extinctions have made it difficult for ecologists to envision the multiple stable states prevailing in evolutionary time. In the absence of their megafauna, the

savannas, grasslands, riparian habitats, and other biotic communities of the New World, Australia, and Madagascar are not functionally "natural."

Prehistoric settlement on deep-water islands in the remote Pacific began 4000 years ago. Extinctions followed, eliminating many endemic birds, reptiles, and land snails along with depletion or size reduction brought by overharvesting of near-shore fish, shellfish, and marine turtles. The relatively small number of oceanic islands that escaped prehistoric discovery suffered losses during historic time of such animals as the dodo, Steller's sea cow, giant rats, and parrots (Figure 2). No late Quaternary extinction pulse is seen in the fossil record of the whales, other marine fauna, or in Antarctica.

An intense and often controversial search during the past 40 years for an explanation for the cause or causes of the LQEE has failed to yield any widespread consensus among paleontologists, archeologists, paleoecologists, geographers, and other interested parties, many of them convinced of the efficacy of climatic change and of climatic extinction models. In recent years, as the global pattern of the LQEE has become better known, much more attention has been focused on anthropogenic models (compare MacPhee (1999) with Martin and Klein (1984)). Always on the scene, humans can no longer be ignored in the search for the cause or causes of "extinctions in near time."

The Comparative Approach

In the view of most geologists the Quaternary or Pleistocene ice age of multiple glaciations embraces at least the past 1.81

Figure 1 Late Quaternary extinction and prehistoric human dispersal; for numerical sequence and estimates of extinction timing, see the legend to **Figure 2** (Reproduced from Martin PS and Steadman DW (1999) Prehistoric extinctions on islands and continents. In: MacPhee R (ed.) *Extinctions in Near Time*, pp. 17–55. New York: Kluwer/Plenum, with permission from Springer.).

million years (Ma), with the late Quaternary representing the past 200,000 years. In North America the late Quaternary includes the Rancholabrean mammalian age stage, marked by the appearance of the genus *Bison*.

With the possible exception of Australasia, most late Quaternary extinctions fall within the reach of radiocarbon assay, essentially the past 40,000 years. Fossils uncontaminated by groundwater and yielding bone collagen or gelatin are suitable for dating. Environments favorable for the preservation of bone collagen include dry caves of arid regions, the frozen ground of high latitudes, lacustrine deposits, and saline or petrolic sediments such as those at Rancho la Brea, California. Burned bone and associated charcoal are ideal for dating, although charcoal may prove intrusive. A variety of geochemical dating methods, especially radiocarbon dating, allow biogeographers to compare both the rate of extinction within a landmass and the timing of extinctions between landmasses. A robust chronology allows intercontinental and insular comparisons of considerable value in inferring cause of the extinctions.

Although details regarding just how the extinctions were triggered remain speculative, it is increasingly clear that the two major contending explanations of what forced LQEE—that is, climatic changes and cultural impacts—can now be evaluated globally. When approached on a comparative basis, human expansion and climatic change track a punctuated extinction episode in North America and perhaps in South America, whereas climatic change is less clearly involved in Australia or Madagascar and appears to be of no significance in New Zealand and other remote Pacific islands.

North America

Focusing on the past 4 million years only (the Pliocene and the Quaternary), it is possible to evaluate the LQEE using age-stage divisions of biostratigraphers (**Table 1**). The overwhelming importance of extinctions of North American large mammals at the end of the Quaternary, shown in **Figures 3** and **4** and in **Table 1**, has been evident for at least the past 50 years.

The widespread adoption of screen washing of fossil deposits has vastly enriched the fossil record of small vertebrates. The harvest of identified small mammals is vital in supporting the conclusion that no appreciable extinctions of small mammals occurred (**Figure 3**)—certainly not matching the extinction spasm of large mammals approximately 11,000 radiocarbon years ago (**Figure 4**).

The fossil record is based on a much larger sample of late Pleistocene than early Pleistocene and Pliocene faunas (**Table 1** and **Figures 3** and **4**). Presumably this accounts at least in part for the increase in number of genera of both large and small mammals in the later part of the record. Although *Mammuthus*, *Equus*, and extinct *Bison* included multiple species, most of the large genera listed in **Table 1** are monotypic (represented by one species only). Although a few survived on other continents, most large genera totally vanished (**Table 1**).

In North America north of Mexico, 33 genera of large mammals disappeared in the late Quaternary, which constitutes two-thirds of the total late Rancholabrean fauna of 48 genera and more than all the generic extinctions recorded during the previous 4 million years prior to LQEE (**Table 1**). Events that might trigger regional or global extinctions in the early part of the past 4 million years include intercontinental suturing of the Americas with faunal intermingling, extra-terrestrial accidents such as the impact of the Eltanin bolide, and the initiation of continental glaciation. However, only at the end of the Quaternary is there a major extinction spasm—one that impoverished America's large mammalian faunas (**Figure 4**).

Unlike the case of the large mammals, a much larger number of small genera (48) vanished in the past 4 million years. Within the minifauna (rat, mouse, or shrew-size mammals), which make up the majority of the 75 living genera of small mammals, no generic extinctions are known in the late Quaternary. Among the medium-sized mammals, three genera were lost: the antilocaprid *Stockoceros*, the skunk *Brachypotoma*, and the rabbit *Aztlanolagus*. The difference deserves close inspection. Although small mammals escaped virtually unscathed, the LQEE (late Rancholabrean losses) blighted all terrestrial orders of large land mammals and eliminated one, the Proboscidea (**Table 1**).

Since the vast majority of Cenozoic (last 65 Ma) extinctions occurred long before radiocarbon time or FC, it is essential to know something of the Cenozoic pattern. Do earlier bursts of extinction match the LQEE pattern at the very end of the Cenozoic? As a result of a relatively rich fossil record of the Cenozoic, the question is readily approached in North America.

Paleontologist John Alroy (cited in MacPhee 1999) recently analyzed 65 Ma of change in mammalian faunas through 1.0 Ma sampling bins. His data consist of extinction time rate series that are computed from a multivariate ordination of 4015 faunal lists from 2415 publications that span the

Late Cretaceous through Sangamonian (last interglacial). The lists can be viewed on the World Wide Web at the North American Mammalian Paleofaunal Database: <http://homebrew.si.edu/nampfd.html>.

According to Alroy (as quoted in MacPhee, 1999, p. 120), standing diversity is defined by

the number of species that cross each boundary between sampling bins, e.g., the time planes at 65.0, 64.0 ... 1.0 Ma. Extinctions are computed by counting the number of species in each cohort that fail to survive until the next time plane. Note that this excludes single-interval species (those that appear and disappear in the same bin), which makes the analysis less vulnerable to sampling artifacts.

Alroy's results indicate that within the past 55 Ma there were more extinctions of large species in the LQEE than there were during any earlier time. The difference in the mean body masses of the victims and the survivors peaks at the end of the Pleistocene (Figure 5).

Although there is a general increase in mean mass of mammals through the Cenozoic, the mean mass of victims (extinct species) is highest in the past 1 million year bin within the Cenozoic (Figure 6), which includes the LQEE. In other words, when compared with 64 turnovers earlier in the Cenozoic, the 65th has a unique property—excessive extinction of large mammals.

With the exception of bison (*Bison*) and deer (*Odocoileus*), the common fossils of large herbivores found in Quaternary deposits before the LQEE are not the bones or teeth of species that survived the extinctions, such as *Alces*, *Antilocapra*, *Cervus*, and *Rangifer*, but rather those that did not, especially *Camelops*, *Cervalces*, *Equus*, *Mammot*, *Mammuthus*, and *Platygonus*

Figure 2 Map silhouettes of continents and islands showing time-transgressive sequence of late Quaternary extinctions and FC. *Africa and Eurasia* (1–3): Sequential extinctions of large mammals during the past 100,000 years including Nauman's elephant and giant deer in Japan [J-2] ca. 30,000 years ago. *Meganesia* (2): Humans arrive and major extinctions occur 30,000–40,000 yr bp; neither event is well-dated or constrained. *Americas* (3): Well-dated evidence for human arrival and for megafaunal extinctions center on 11,000 yr bp (13,000 calendar years). *Mediterranean islands*: Epipaleolithic arrival and dwarf hippo and dwarf elephant extinction on Cyprus (3) 10,500 yr bp; mid-Holocene colonization and extinction of goat antelope (*Myotragus*) on the Balearic Islands (4); FC and LQEE chronology elsewhere are uncertain. *Antilles*: Humans arrive in Cuba and Hispaniola in early or mid-Holocene (4) and in Jamaica and the Lesser Antilles in the late Holocene (5); few radiocarbon dates on extinctions. *Madagascar* (5): Humans arrive 2000 yr bp; major episode of extinction terminates 1500 AD. *Mascarenes*, east of Madagascar (6): Humans arrive 1600 AD, followed by extinctions of dodo, solitaire, other birds, and giant tortoises. *New Zealand* (5): Humans colonize by 1200 AD; the Polynesian rat perhaps colonized much earlier. Giant flightless birds (moas) are extinct by 1500 AD. *Wrangel Island* (5): Last woolly mammoths dated 4000 yr bp, 1000 years older than oldest cultural material. *Commander Islands* (6): Humans arrive 1741 AD; Steller's sea cow extinct within 30 years. *Galapagos Islands* (6): Bishop of Panama arrives 1535 AD; extinction rates increase over background by two orders of magnitude (Reproduced from Martin PS and Steadman DW (1999) Prehistoric extinctions on islands and continents. In: MacPhee R (ed.) *Extinctions in Near Time*, pp. 17–55. New York: Kluwer/Plenum, with permission from Springer.).

New York: Columbia Univ. Press.

(Graham and Lundelius, 1994). All have terminal radiocarbon records at approximately 11,000 years ago (Stuart, 1991). One might imagine that if the LQEE were a natural catastrophe the ranges of the Holocene survivors (15 species listed in Table 1) would have expanded rapidly as niche space opened following extinctions. For example, if some lethal climate condition at the end of the last glaciation eliminated their North American relatives, one might expect that afterward early Holocene warming would see the surviving populations of bison, elk, and moose expanding or at least maintaining their range. In fact, bison range shrank away from both coasts (Graham and Lundelius, 1994). Only in recent years, with the help of local introductions by game departments, has the local range and numbers of moose, elk, and black bear expanded.

The historic fauna of bison, deer, moose, elk, pronghorn, bears, wolves, etc. is traditionally regarded as the “natural” fauna of North America. However, the view from the past shows that they are an aberrant, extinction-pruned remnant,

unrepresentative of the diversity or the ecological amplitude of native large mammals that the continent supported during the latter half of the Cenozoic. To view free-ranging bison, deer, moose, elk, pronghorn, bears, and wolves, the protected fauna of Yellowstone National Park in Wyoming or Denali National Park in Alaska, as representative of an American Serengeti is to seriously underestimate the diversity, productivity, and evolutionary potential of the continent.

South America, Australia, and Madagascar

The continents of South America, Australia, and Madagascar share a common property with North America—heavy extinction of large mammals late in the Quaternary. South America lost all large mammals more massive than a tapir (300 kg); Australia lost all mammals larger than a gray kangaroo (60 kg); and, excepting the bush pig which may have been introduced, Madagascar lost all terrestrial vertebrates

Figure 3 North American small mammal originations (dotted line), extinctions (solid line), and total fauna (dashed line) since the Miocene from data shown in Table 1. Note the change of scale in the past 0.5 Ma (Reproduced from Martin PS and Steadman DW (1999) Prehistoric extinctions on islands and continents. In: MacPhee R (ed.) *Extinctions in Near Time*, pp. 17–55. New York: Kluwer/Plenum, with permission from Springer.).

Figure 4 North American large mammal originations (dotted line), extinctions (solid line), and total fauna (dashed line) since the Miocene from data shown in Table 1. Note the change of scale in the past 0.5 Ma (Reproduced from Martin PS and Steadman DW (1999) Prehistoric extinctions on islands and continents. larger than the living *Indri*, a lemur which weighs 7–10 kg. Timing of the extinctions varies; it was earliest in Australia, later in South (and North) America, and latest in Madagascar. Although Australian small mammals (0.5–2.0 kg) suffered historic losses, there is no indication that severe late Quaternary extinction of small mammals accompanied the loss of large ones on the continents.

South America

The Quaternary of South America includes the Ensenadan and Lujanian land mammal ages dated at 1.5 to 0.5 and

0.5 to 0.01 Ma, respectively. The preceding Uquian land mammal age from 2.5 to 1.5 Ma is of great interest because it immediately follows the intercontinental suturing of North and South America. The Uquian shows the effects of the famous Great American Faunal Interchange, a natural experiment in which two continents exchanged long-isolated terrestrial faunas across a new land bridge. The land bridge connecting the continents at the end of the Pliocene brought Northern Hemisphere carnivores, gomphotheres, artiodactyls, and perissodactyls into contact with South American endemic orders, the xenarthrans, notoungulates,

Figure 5 Diversity and extinction in the Cenozoic Data are prepared by multivariate ordination and randomized subsampling. The figure plots the correlation among 1.0-Ma intervals between extinction intensity and the difference in the mean body masses of the victims and the survivors. The end Pleistocene value (●) is among the highest during the past 55 Ma (Reproduced from MacPhee R (ed.) (1999) *Extinctions in Near Time*. New York: Kluwer/Plenum, with permission from Springer.).

Figure 6 Trend through the Cenozoic in the mean body mass of victims and survivors in each 1.0-Ma interval (see legend to Figure 5) (Reproduced from MacPhee R (ed.) (1999) *Extinctions in Near Time*. New York: Kluwer/Plenum, with permission from Springer.).

and litopterns. Interestingly, millions of years before the intercontinental conjunction, megalonychid ground sloths managed to colonize both the Greater Antilles and North America.

Occasionally, biogeographers have sought to invoke intercontinental exchange as a cause of the LQEE. A detailed summary of the South American fossil faunas by Marshall and Cifelli (1990) shows that although small-mammal extinctions occurred in the Uquian, heavy megafaunal extinction did not occur until the Lujanian, approximately 2 million years after the exchange had begun and apparently coeval with the LQEE in North America.

South American extinctions of the late Quaternary were even heavier than those in North America north of Mexico,

involving 50 genera of which 35 belong to extinct families. The losses were differential and involved all megaherbivores such as giant ground sloths, glyptodonts, gomphotheres, and two endemic orders, Litopterna and Notoungulata (Table 2). It is not obvious that the interchange had anything to do with the LQEE.

Defensible radiocarbon dates on most of the South American fauna remain to be assembled and may be difficult to obtain given the poor preservation of bone collagen in the open sites where Lujanian faunas are often found. One source of ideal material for radiocarbon dating—dung, hair, and perishable tissue—has been obtained on mylodontid ground sloths from Cueva del Mylodon in southern Chile. Fifteen dates from 13,000 radiocarbon years before present (yr bp) to 10,600 yr bp support the extinction chronology for ground sloths in North America.

Australia

Flannery and Roberts (cited in MacPhee, 1999) report that near the time of first contact (FC) Meganesia (Australasia) lost approximately 28 genera and 55 species of large vertebrates (body weights exceeding 10 kg). The more important extinct genera of mammals in the Australasian (Australia and New Guinea) extinct megafauna are all marsupials. They include the extinct "lion" *Thylacoleo*; the wombats *Phascolomys*, *Phascolonus*, and *Ramsaya*; a Palorchestid, *Palorchestes*; four diprotodontids—*Diprotodon*, *Euwenia*, *Nototherium*, and *Zygomaturus*; a potoroid, *Propleopus*; and five giant kangaroos—*Fissuridon*, *Procoptodon*, *Protemnodon*, *Sthenurus* and *Troposodon*. In addition, there was an extinct giant flightless bird, the mihirung (*Genyornis*); a giant lizard, *Megalania*; an extinct horned turtle, *Meiolania*; and a giant python, *Wonambi*. Although older, the pattern of extinction in Australia resembles that in the Americas and Madagascar. In all three landmasses kill sites or processing sites are few, in dispute, or absent. As elsewhere, the lack of kill or butchering sites has deterred many Australian archeologists and paleontologists from invoking an overkill. Although no extinctions of Australian mammals less than 10 kg are known at FC, a sizable number of medium-size mammals are threatened or have vanished in historic time, presumably a side effect of European settlement in Australia (Flannery, 1994).

Despite the problem in direct radiocarbon dating on extinct fauna, the absence of extinct species from well-dated Tasmanian archeological sites up to 25,000 years in age supports the view that the Australian LQEE was over by then. The Franklin River region in Tasmania serves as an example. As in other parts of eastern Australia, Tasmania once harbored a variety of extinct species of giant marsupials. Although 21 dated late Pleistocene sites in caves or rock shelters in southwestern Tasmania ranging in age from 10,000 to at least 25,000 yr bp have yielded hundreds of thousands of animal bones, all are of living species and mainly of Bennett's wallaby, *Macropus rufogriseus* (J. Allen as cited in Kirsch and Hunt, 1997). If the extinct mihirung, giant macropods, diprotodonts, etc. were still alive 25,000 years ago or later, it is difficult to believe that they would not be represented in such rich zooarcheological material. This negative evidence supports the view that extinctions occurred earlier.

Until more fossil faunas are dated, there will be unavoidable uncertainty about when extinction occurred. In this regard, new environmental information from stable isotopes from samples of *Genyornis* eggshell is especially promising. The record to date indicates extinction of *Genyornis* by 45,000 yr bp in several parts of its wide range and in more than one climatic province; these findings argue against extinctions driven by some climatic bottleneck (Miller *et al.*, 1999). In Australia extinctions long predate any hypothetical late glacial climatic forcing.

Finally, in terms of human origins, a comparison between Australia and America is instructive. In the New World archeologists have seen a variety of sites claimed to be 13,000–22,000 years or older fail to be verified or locally replicated, despite regular assertions of their proponents. In contrast, in the past two decades dozens of Australian sites have repeatedly yielded geochemical dates indicating dozens of sites older than Clovis in North America.

Given the smaller area of Australia compared with that of the New World, its much less productive soils and much more variable precipitation (Flannery, 1994), and the much smaller number of archeologists, geologists, paleontologists, and amateurs searching for artifacts and fossils, the abundance of sites 10,000–40,000 years old and older in Australia, compared with the half a dozen claims of pre-Clovis sites in the New World and their debatable status, is a red flag to environmentalists. Unless proposed early sites in the Americas are critically replicated by the geoarcheological community at large, as in Australia, the claims for a pre-Clovis occupation and a pre-Clovis culture, no matter how detailed or how often repeated, remain in limbo (Martin and Steadman, 1999).

Madagascar

Within the past two millennia, at a time when no other continents suffered appreciable extinctions of large mammals (Martin and Klein, 1984), Madagascar lost many large mammals, including 20 species of lemurs up to the size of a gorilla. All are larger than the largest living lemurs. In addition, Madagascar lost two hippos; the highly endemic anteater known as bibymalagasy (*Plesiorycteropus*), recently assigned to its own order; a large (bobcat-size) species of carnivore (*Cryptoprocta spelea*); a rabbit-size rodent (*Hypogeomys australis*); two genera of giant flightless birds; and two giant tortoises, one exceeding 100 kg in mass (MacPhee and Marx as cited in Goodmans and Patterson, 1997). Although most if not all of these extinctions in Madagascar coincide with human colonization, none have been found in well-defined kill sites, leading MacPhee and Marx to model hyperdisease. They generalize their model to include all lands of prehistoric human colonization. Despite its implausibility, the model invites testing since the fossil record has yet to reveal how LQEE occurred. In the Americas the lack of many Clovis kill sites may be overcome by modeling "blitzkrieg," a rapid elimination of preferred prey, leaving minimal field evidence, by a potent human predator (Martin, 1990).

If aridification contributed to extinctions in Madagascar, it was evidently a potential problem only in the southwest. Sudden overkill by a "blitz," a sweep of the vulnerable megafauna, seems unlikely if the start-up of colonization took more than 1000 years. Robert Dewar (as cited in Goodman and Patterson, 1997) suggested that the impact of wild cattle on the native fauna rather than human hunting forced the extinctions.

All this may be resolved eventually by enrichment of the stratigraphic and geochronological record, including a major effort at extending the radiocarbon chronology of the extinct Malagasy megafauna into glacial times to determine if late glacial climatic change forced extinctions long in advance of human presence. Radiocarbon dates of 13,000 and 26,000 yr bp on a large (~70-kg) extinct lemur, *Megaladapis* (Simons as cited in Goodman and Patterson, 1997), indicate that glacial-age faunas exist. Apart from *Megaladapis*, virtually nothing is known of the glacial-age faunas of Madagascar. Like other extinct genera, *Megaladapis* survived until the end of the Holocene and may have been known historically.

Unlike Madagascar, rich glacial-age faunas are known in New Zealand, Tonga, and Hawaii. To date, no glacial-age extinctions have been detected in these islands, strengthening

the case for an anthropogenic agency as the unique cause of LQEE (Martin and Steadman, 1999).

Perhaps the most interesting case of comparative extinctions is the global decline of giant tortoises. Giant tortoises can be regarded as extremely vulnerable to human foragers. They survived historically only on remote warm-water oceanic islands that escaped prehistoric colonization, such as the Mascarenes, Seychelles, and Galapagos. In the late Holocene in Madagascar, giant tortoises vanished with the giant lemurs. In Africa they disappeared much earlier, perhaps more than 2 million years ago, an event that may represent the earliest example of an anthropogenic forcing of megafaunal extinctions.

Eurasia and Africa

Compared with the sweeping, catastrophic loss of late Quaternary megafauna in the New World, Madagascar, and arguably Australia, the losses in Eurasia were relatively minor and they occurred gradually (Figure 7; Martin and Steadman, 1999; Stuart, 1991). Outside the tropics, the extinct Eurasian fauna can be divided into two parts. One was a "warm" or interstadial fauna with straight-tusked elephants (*Elephas (Palaeoloxodon) antiquus*), temperate rhinoceroses (*Stenorhinus hemitoechus* and *S. kirchbergensis*), hippo (*Hippopotamus amphibius*), and a cave bear (*Ursus spelaeus*). The other was a "cold" or stadial fauna with woolly rhinoceros (*Coelodonta*

Figure 7 Extinction or extirpation chronology of large mammals in northern Eurasia. Note how the inferred extinction dates are very staggered compared with the strong pulse of extinctions in North America (right). During at least 50,000 yr bp the loss of Eurasian large mammals was sequential; the loss in North America was sudden. NE, northern and central Europe; It, Italy; Ja, Japan; SF, southern France; Sp, Spain; Lv, Levant; E, England; Sc, Scandinavia; Ir, Ireland; NS, north-central Siberia; *Elephas (Palaeoloxodon) antiquus*, straight-tusked elephant; *Hippopotamus amphibius*, hippopotamus; *Stenorhinus hemitoechus* and/or *S. kirchbergensis*, temperate rhinoceroses; *Ursus spelaeus*, cave bear; *Crocuta crocuta*, spotted hyena; *Coelodonta antiquitatis*, woolly rhinoceros; *Megaloceros giganteus*, giant deer; *Mammuthus primigenius*, woolly mammoth (Reproduced from MacPhee R (ed.) (1999) *Extinctions in Near Time*. New York: Kluwer/Plenum, and Stuart AJ (1991) Mammalian extinctions in the Late Pleistocene of Northern Eurasia and North America. *Biol. Rev.* 66: 453–562.).

antiquitatis), woolly mammoth (*Mammuthus primigenius*), and musk ox (*Ovibos moschatus*). This stepwise sequence of change in temperate and boreal faunas of Eurasia is gradual compared with the sudden extinction of both cold- (woolly mammoths and woodland musk oxen) and warm-adapted species (tapir and jaguar) in North America.

Intriguing differences in the pattern of Old and New World extinction are best illustrated in the case of proboscideans. Extinction of straight-tusked elephants did not begin until early in the last cold stage of the late Quaternary. Extinct throughout their European range by 60,000 years ago (Stuart, 1991), *Elephas* persisted in Japan until 30,000 years ago or less. The largest Holocene survivors in the megafauna of Japan were Sika deer (*Cervus*), wild boar (*Sus*), and black bear (*Selenarctos*). Although dwarf relatives of *Elephas* evidently did not survive on Mediterranean islands as late as the Holocene, as was once thought (Martin and Klein, 1984), mid-Holocene woolly mammoths have been found on Wrangel Island off Siberia, 6000 years younger than any other known mammoths—contemporary with the Pharaohs. The Akrotiri *Aetokremnos* bone cave, an epipaleolithic site on Cyprus, yielded dwarf straight-tusked elephants along with abundant bones of dwarf hippo. The deposit is radiocarbon dated at 10,500 years old. Just as Wrangel Island served as a refugium for the last of the boreal woolly mammoths, thousands of years after they were extinct throughout the rest of their range, Japan and Cyprus apparently sheltered the last populations of temperate Eurasian *Elephas* long after its extinction on the continent (Martin and Steadman, 1999).

Unlike the slow pace of extinction of the Proboscidea in northern parts of Eurasia, in North America prior to an extinction spasm 10,000–11,000 yr bp the animals suffered no loss of taxa, no clear-cut reduction in range, and no apparent decline in numbers (see maps in Graham and Lundelius, 1994). Had American Proboscidea followed the Old World extinction pattern for elephants, the temperate elephant of midlatitudes, the Columbian mammoth, would have predeceased high-latitude extinction of woolly mammoths by tens of thousands of years while the order would endure in tropical America, represented by a living species.

Both ivory carvings and cave paintings depicted by Stone Age artists reveal their intimate knowledge of the anatomy and behavior of Old World woolly mammoths and many other animals. Although field evidence of mammoth kills is scarce, low rates of increase of modern megaherbivores means that modern elephants, rhinoceros, and hippo would have been highly vulnerable to human predation (Owen-Smith, 1988). Even with governmental protection in this century, the future of surviving megaherbivores is by no means ensured. The gradual decline of Eurasian mammoths could readily have resulted from a minimal amount of human hunting or interference, especially if younger age classes were targeted.

Although the nature of the association and its meaning in modeling insular faunal extinctions in the Mediterranean are uncertain, the record at Akrotiri *Aetokremnos* suggests a Paleolithic “commando raid” in which Stone Age hunters or foragers overran an island, slaughtered preferred prey (dwarf hippo, dwarf elephant, and endemic deer), did not find sufficient resources for a sustainable economy, and soon left with no other evidence of their passage besides the remarkably rich

contents of one cave. Possibly Crete, Ireland, Wrangel Island, and the Channel Islands of California also lost megafauna to commando raids that left scant evidence or at least none discovered to date. Given the scarcity of convincing kill or processing sites on continents, the rarity of such features on offshore islands is not surprising. Only in the remote Pacific such as on the low limestone islands in Tonga are extinct animals (bones of megapodes) abundantly associated with artifacts of the first colonists. In other cases (Hawaii and Madagascar), such associations are rare or unknown (MacPhee, 1999).

Africa has been held up to modelers of overkill as a conundrum. If people are such effective exterminators, how did the African megafauna survive? However, the argument cuts two ways. If late Pleistocene climatic change played a major role in triggering megafaunal extinctions elsewhere, how did so many large animals manage to survive in Africa and Asia, continents no more immune to Pleistocene climatic change than other corners of the globe?

One reply to the conundrum is that in Africa and Asia there was sufficient time to evolve a balanced predator-prey relationship, perhaps with human populations locally suppressed by sleeping sickness and other endemic human diseases and on occasion by intertribal buffer zones (Martin and Klein, 1984). The extinction record in both Africa and Asia is so unlike that found elsewhere on the planet that important differences in historical biogeography and human ecology may be postulated. The record of gradual human evolution and radiation confined to the Afro-Asian landmass, ending in the late Quaternary with explosive expansion of human colonists onto all other temperate landmasses, fits the model of a time transgressive overkill.

Oceanic Islands

Late Quaternary losses were limited neither to continents nor to mammals. They swept through oceanic islands. For example, on the larger oceanic islands the extinction of large terrestrial vertebrates included flightless moas in New Zealand; gorilla-size extinct lemurs, extinct hippo, giant tortoises, and giant flightless birds such as *Aepyornis* in Madagascar; house cat to bear-size ground sloths in the West Indies; dwarf elephants and dwarf hippo on islands of the Mediterranean; and dwarf elephants and/or giant tortoises on oceanic islands beyond the continental shelf in southeastern Asia such as Timor, Flores, and Sulawesi. In one unusual case, prehistoric extinction only 4000 years ago eliminated elephants (woolly mammoths) not from a deep-water island but from a shelf island, Wrangel, in the Arctic Ocean (Figure 2).

With their discovery 25 years ago on Hawaii of a flightless goose (*Thambetochen*) and a flightless ibis (*Apteribis*), ornithologists Alexander Wetmore and Storrs Olson triggered the search for unknown extinctions on Pacific archipelagos. In the following years, archeologists and paleoecologists began to uncover rich fossil faunas reflecting prehistoric (Holocene) extinctions. During the past two decades their efforts on the Cooks, the Marquesas, the Kingdom of Tonga, and the Line Islands, to name a few examples from the South Pacific, have yielded many extinct species of small birds, especially flightless

rails, pigeons, and parrots (Steadman, 1995; Steadman as cited in Kirch and Hunt, 1997).

On the basis of fossil deposits from a sample of the 800 islands in the Pacific that are more than 1 km² in area, Steadman (1995) estimates the loss of 10 species or populations from each—a total loss of 8000 species or indigenous populations of land birds (including an estimated 2000 endemic species of taxonomically distinctive flightless rails). In addition to human harvesting and possible surplus killing, the introduction of Pacific rats may have eliminated many flightless rails and other birds. In some cases, the rats may even have colonized in advance of their human vectors (Holdaway as cited in MacPhee, 1999).

Extensive colonies of petrels, shearwaters, and other seabirds vanished from many Pacific islands, dimming the avian beacon which helped guide the prehistoric explorers to remote uninhabited islands (Steadman as cited in Kirch and Hunt, 1997). The fossil records of the relatively small number of islands that experienced FC and heavy extinction within historic time, such as the Galapagos, the Mascarenes, and remote Atlantic Islands such as St. Helena, have yet to reveal any pulse of prehistoric (Holocene) extinctions to match those found on islands that were colonized prehistorically.

New Zealand provides the best fossil record of island extinctions, starting with the loss of flightless wrens and small petrels, which were eliminated by accidental Polynesian introduction of Pacific rats (*R. exulans*), and beginning perhaps 1000 years in advance of Polynesian settlement. After Captain Cook's arrival in 1770, more species of mammalian predators reached New Zealand, including the dog, Norway rat, feral pig, feral cat, house mouse, black rat, ferret, and stoat (Holdaway as cited in MacPhee, 1999).

To bring prehistoric extinctions into focus, it is necessary to scan the globe and to probe the magnitude, timing, pattern, and natural history of all prehistoric losses on all landmasses, continents, and islands. This simple comparative approach in paleontology opens new vistas—ones that the popular MacArthur–Wilson model of island biogeography, based on modern distributions, will not reveal. High rates of vertebrate extinction on oceanic islands in the past five centuries, the focus of attention by conservation biologists (MacPhee and Flemming as cited in MacPhee, 1999), pale in magnitude to the extinction spasm of the previous four millennia.

Can extinctions of the LQEE be reversed? They certainly can if we do not insist on replacing lost species with taxonomically identical populations. On oceanic islands restoration ecologists need to consider restarting evolution of lost lineages of rails, using Guam rails on islands once occupied by flightless rails. In North America, a Pleistocene park should minimally include proboscideans, camelids, and equids as well as bison and other historic megafauna that survived the LQEE.

Pattern and Cause

Through an understanding of the pattern and timing of late Quaternary extinctions it may be possible to establish their cause. As the chronology, stratigraphy, paleoecology, and global pattern of the extinctions become better known,

the ultimate questions of rate are clarified. For example, Darwin's view in *Origin of Species* that prehistoric extinctions of large mammals occurred gradually and sequentially is supported by the LQEE in Eurasia (Figure 7). Although an extraterrestrial accident such as an asteroid or cometary impact is often linked to some earlier mass extinctions, especially at the end of the Cretaceous, the space rock scenario can be ruled out in the late Quaternary. Over radiocarbon time the global pattern of loss was sequential or time transgressive, from more than 30,000 years ago in Australia to 1000 years ago in New Zealand (Figures 1 and 2), virtually eliminating any possibility of a one-shot global climatic catastrophe, such as a unique lethal cold snap, hyperdrought, or a great flood.

The prehistoric extinctions reviewed here are increasingly suspected of being the preamble of a vastly larger number to follow, a true mass extinction event in the making. Its cause would be anthropogenic.

Anthropogenic Models

The two major competing hypothesis or models to LQEE involve either anthropogenic or climatic forcing or both in combination (Burney, 1993; MacPhee, 1999; Martin and Klein, 1984). The anthropogenic model includes a variety of possible human impacts: direct overkill, surplus killing, a predator pit (doomed but still functioning predators, such as saber cats, reinforcing human predation), introduction of pandemic disease ("hyperdisease"), and human-initiated changes in habitat. The anthropogenic model is based on the close timing of extinctions to the global spread of anatomically and behaviorally modern people. In addition, some propose that Neanderthals or earlier hominids also had a role both in shaping the evolution of large mammal communities in the Old World and in the extinctions of the most vulnerable prey species providing rich resource packages such as giant tortoises, animals whose antipredator strategies were ineffective against humans. The kinds of animals lost in the LQEE appear to represent species known to be or likely to have been preferred prey.

A new player among the possible contenders for anthropogenically driven LQEE pulses is infectious disease, brought in at FC by human colonists themselves or, more likely, everything and anything that came along with them, such as domesticated, commensal, and synanthropic species. Especially on oceanic islands, the impact of human colonists would be amplified by the introduction of aliens, such as the Pacific rat *R. exulans*, chickens, domestic pigs, and dogs, along with their exotic diseases. The logic of hyperdisease is similar to that of classic overkill, but it contemplates humans as passive rather than active agents in causing faunal crashes. The basic idea is that "emerging" diseases, introduced into species without any natural immunity to them, would have induced incredible levels of mortality in susceptible populations, conceivably leading to their extinction. Once a "new" infectious disease process got started in a susceptible population, it would run its course quite independently of the rate or direction of human expansion.

Critics of anthropogenic models note that kill sites indicating human predation on and processing of allegedly preferred prey are rare, with few in the Americas and none in Australia or Madagascar and few in the Americas. The case of Madagascar is especially curious because its losses occurred only within the past 2000 years. Skeptics challenge the chronology of extinction, denying that within North America or Australia all extinct large mammals vanished abruptly, on the heels of human colonization, as implied by overkill. Some contend that humans arrived in both continents significantly before extinctions occurred. If human arrivals triggered megafaunal extinctions in the New World and Australia, critics ask, how do we explain the coexistence of *Homo sapiens* and large mammals in Africa and tropical parts of Eurasia? Vertebrate paleontologists have traditionally appealed to climatic or environmental changes as the main forcing function for many mammalian extinctions. During the past 65 million years the vast majority of extinctions occurred before any possibility of human involvement.

Climatic Models

Climatic models are based on the highly variable nature of late Quaternary environments with rapid switches from cold or cold and dry to warm and wet accompanied by changes in CO₂ pressure. In some cases, such as the Allerød–Younger Dryas shift within the late glacial, the switch appears to coincide with megafaunal extinctions, especially in North America. At least one habitat, the steppe–tundra of polar regions in the Northern Hemisphere, has been identified as an extinct biome (Guthrie as cited in [Martin and Klein, 1984](#)) whose end doomed woolly mammoths and other subarctic megafauna. Some LQEE models invoke a switch from less extreme to more extreme seasonality with out-of-step breeding cycles eliminating ruminants whose life cycles could not accommodate the climatic changes (Kilte and Graham and Lundelius as cited in [Martin and Klein, 1984](#)).

Critics discount late Quaternary climatic change as a forcing function since the paleoclimatic record of the Quaternary is rich in rapid and severe changes long before as well as during episodes of extinction. Fewer megafaunal extinctions occurred in the 3.5 million years combined, before human arrival, than in the late Quaternary, suggesting that species in Quaternary biotas were buffered against environmental switches typical of the last ice age. In any case, a late Quaternary extinction spasm is not evident in the oceans or in freshwater habitats and involves small animals only as parasites or on oceanic islands on which the reduced area would have amplified human impacts. Finally, the character of LQEE universally points to species that would either be preferred

prey for human foragers and predators or be vulnerable (as in the case of minute endemic island snails) to aliens introduced from the continent.

Although details of how prehistoric humans might have triggered prehistoric extinctions are not easy to interpret from the fossil record, on a global scale the LQEE strongly reflects a deadly syncopation between extinction and human arrival. Viewed from the Cenozoic, Alroy (as quoted in [MacPhee, 1999](#), p. 105) observed,

The event's timing, rapidity, selectivity, and geographic pattern all make good sense according to the anthropogenic model and no sense at all otherwise. I believe that the overkill hypothesis, at least in general terms, already has been "proven" as thoroughly as any historical hypothesis can be.

Glossary

Benthos Organisms living on or in sediment, below the water.

Extinction The disappearance of a species upon death of its last surviving individual. In the fossil record, this is treated as the last fossil occurrence of individuals of a species.

Foraminifera An order of animal-like protists, many of which secrete calcareous skeletons (“tests”).

Mass extinction The simultaneous extinction of a disproportionate number of species over timescales of 10^0 to 10^6 years resulting in loss of biodiversity.

Phanerozoic The geological interval of abundant animal fossils, beginning approximately 545 million years ago.

Stratigraphic section An outcrop of rock (with fossils in this case) or a drilled core. The term can also refer to a composite for a region in which fossil ranges and stratigraphic events have been summarized into a synthesized rock column.

Tetrapod vertebrates Vertebrate animals with four limbs (or vertebrates that have evolved from such animals, such as snakes).

History of the Concept

The concept of extinction of species goes back at least several centuries. The extirpation of aurochs (wild relatives of cattle) and disappearance of lions from Europe were well known in the era of enlightenment and ascribed to human interference. The fact that species could become extinct from nonhuman causes was promoted by Cuvier at the end of the 18th century through his exquisitely detailed studies of mammalian fossils of the Paris Basin. His arguments were not accepted by all intellectuals at the time, and, in fact, Thomas Jefferson, the third president of the United States, doubted species could disappear before humans; he assigned Lewis and Clark a secondary mission in their explorations of the American northwest to search for living mammoths and mastodons.

The division of sequences of sedimentary rock into geologic systems by British geologists and paleontologists in the first half of the 19th century reflected a concept of major changes in marine faunas between these still-used time periods. But the first quantitative depiction of mass extinctions—major declines in biodiversity followed by recovery—appears to be Phillips's (1860) count of known numbers of fossil species and interpretive graphing of massive drops in diversity between the Paleozoic and Mesozoic eras and the Mesozoic and Cenozoic eras (terms he coined; see Figure 1).

The study of mass extinctions rested largely in limbo from Phillips's pioneering work into the mid-20th century. This was perhaps because of emphasis on documenting evolutionary continuity in the fossil record and an assumption of substantive uniformitarianism, inherited from Lyell. However, with accumulation of paleontological data, the greatest of all Phanerozoic mass extinctions—the end-Permian, or

“Permo-Triassic,” event—could not remain unnoticed. Schindewolf (1963) wrote a seminal paper discussing this event and invoking lethal radiation from an extraterrestrial catastrophe of a nearby supernova explosion. In response, Newell (1967) carefully counted fossil taxa (mostly described families) and argued that there were at least five events of mass extinction in addition to the Permo-Triassic. These papers set the stage for modern studies: examining detailed biostratigraphic data on local species disappearance and global compilations of taxonomic ranges.

Despite the contributions of Schindewolf and Newell, work on mass extinctions remained largely a “cottage industry” among paleontologists until 1980. Workers would examine one of Newell's events (usually in isolation of others) and posit some associated physical event as the cause, such as fall of sea level, or invent ad hoc hypotheses, such as heavy metal poisoning in the oceans as a result of mountain building.

Maturation of the study of mass extinction came with the bold hypothesis of Alvarez *et al.* (1980) that the Mesozoic-Cenozoic event, recognized 120 years before by Phillips, was caused by impact of a 10-km meteorite. The initial evidence of Alvarez and coworkers was concentration of the rare terrestrial element, iridium, at solar-system abundances in a clay layer at the Cretaceous-Tertiary boundary. But the hypothesis implied other testable questions: (a) Is there additional physical evidence of an impact at the Cretaceous-Tertiary boundary and (b) Is the abruptness of biological extinctions at the event consistent with a catastrophe induced by meteorite impact? Impressive evidence affirming the first question has been assembled, including global identification of the iridium-rich clay layer (in both marine and terrestrial stratigraphic sections); presence of shocked mineral grains (e.g., quartz), microspherules of shock-melted minerals, and abundant soot in the global clay layer; and the presence at 65Ma of the largest

[†]Deceased.

Figure 1 The first diversity curve for fossil organisms (a) compiled by Phillips (1860) compared to a late-20th century diversity curve for fossil marine animals (b). While Phillips' curve was generalized and based on comparatively few described taxa, the end-Permian mass extinction (between the Paleozoic and Mesozoic eras) and end-Cretaceous mass extinction (between the Mesozoic and Cenozoic ("Ceno") eras) were recognized. The lower graph illustrates three additional mass extinctions among those recognized by Newell (1967): the end-Ordovician, Late Devonian, and end-Triassic. Abbreviations along the abscissa for geologic time in (b) and in other figures are V = Vendian; C = Cambrian; O = Ordovician; S = Silurian; D = Devonian; C = Carboniferous; P = Permian; Tr = Triassic; J = Jurassic; K = Cretaceous; T = Tertiary. In: Schopf JW and Klein C (eds.) *The Proterozoic Biosphere: A Multi-Disciplinary Study*, pp. 525–527. Cambridge: Cambridge University Press.

impact crater known from the Phanerozoic in the Yucatan, Mexico. Answers to the second question have proved more difficult and will be considered later.

The recognition of extinction events in the geologic past demands comparison to modern extinctions, from the auroch to the myriad other species documented to have disappeared from human interference. Questions include not only how modern rates of extinction compare to those in the fossil record but also the consequences of extinction: What kinds of organisms are most susceptible to extinction and what are the patterns of biotic recovery after the pressure of extinction has

been removed? These questions will be considered further later in this discussion.

Models of Mass Extinction

A variety of patterns of extinction have been observed in the fossil record around events, ranging from abrupt termination of species at an extinction level to gradual disappearance up to it, and perhaps beyond, the extinction level. Three scenarios for mass extinction have been proposed based on empirical observations: abrupt extinction, gradual extinction, and stepwise extinction.

Abrupt Extinction

This is the pattern hypothesized by Alvarez *et al.* (1980) of species disappearing in a geologic instant (which could in fact be 10^1 to 10^3 years). Observed declines in diversity before the event (such as seen in detailed records of foraminifera or broader records of dinosaurs before the Cretaceous-Tertiary) are a result of the Signor-Lipps sampling effect (discussed later).

Gradual Extinction

The fossil record is taken on face value, especially if there has been extensive sampling around the horizon of extinction. Slow attrition of species up to the end of a mass extinction has been claimed for extensively sampled foraminifera around the Cretaceous-Tertiary event, where several large, but rare foraminifera seem to disappear below the stratigraphic boundary and some small, generalized foraminifera occur above the boundary.

Stepwise Extinction

The fossil record is again taken at face value but exhibits a series of pulses of species terminations. This pattern has been hypothesized for situations such as the Late Devonian mass extinction ("upper Kellwasser Event") where intensively sampled taxa of different groups appear to disappear in small pulses separated by 10^4 to 10^5 years. The model can be expanded to intervals such as the end-Ordovician (the second largest marine mass extinction of the Phanerozoic) when many trilobites and other marine animals of tropical areas appear to become extinct at the onset of major glaciation, and then, perhaps 10^6 years later, surviving deep-shelf benthos disappear as normal conditions of low oxygen return with the end of glaciation. (In this case, each pulse of extinction could be dissected to determine if it had been abrupt, gradual, or stepwise at finer timescales.)

These scenarios need to be distinguished from the low levels of extinction that are observed in all geologic intervals. These levels are normally termed "background extinction" to distinguish them from events of mass extinction. Background extinction for marine animals appears to decline through Phanerozoic time. Thus, smaller extinction events are more obvious in Newell-type data over the Mesozoic and Cenozoic eras than during the early Paleozoic when background rates were high.

Interpreting Data from the Fossil Record

The fossil record provides direct evidence of previous mass extinction but only an incomplete accounting because of differences in preservability of organisms (e.g., bivalve mollusks versus polychaete worms) and in scientific sampling (e.g., Europe and North America versus Antarctica). With an incomplete record, observed last occurrences of fossil species are only a minimum estimate of actual times of extinction. This consideration was formalized for mass extinction by Signor and Lipps (1982) who modeled how observed terminations of species would appear around an abrupt extinction (Figure 2). With less intensive sampling or less complete preservation, the expectation is a pattern of gradual disappearance of fossil species up to a boundary of abrupt mass extinction. This sampling pattern holds true whether one is examining detailed stratigraphic sections of fossils or analyzing compilations of fossil taxa, like those of Newell.

Raup presented a very intuitive example of the Signor-Lipps effect (Figure 3). He used data collected for ammonites below the Cretaceous-Tertiary boundary to investigate how the fossil record of extinction would have appeared if the mass extinction had occurred at an interval 100 m lower in the stratigraphic section. (A meteorite impact or other unpredictable catastrophe potentially could occur anywhere in a stratigraphic section.) The decline in observed diversity up to the artificial event does not appear substantially different from the gradual decline of diversity actually observed below the true Cretaceous-Tertiary boundary. This suggests that problems of variable preservation and incomplete sampling of fossils can indeed influence empirical patterns of species disappearance

Figure 2 Hypothetical and calculated diversity curves reflecting the “Signor-Lipps effect”—that is, imperfect sampling around a catastrophic mass extinction. The dashed curve represents true diversity, which is treated as constant until time unit 4 at which there is a catastrophic mass extinction reducing diversity by three-quarters. If fossil taxa are not sampled up to the times of their true extinctions, declines in diversity will appear more or less gradual, depending on the intensity of sampling. Curve a represents the poorest sampling, and curve c the best (three times better than a). Reproduced with permission from Signor PW and Lipps JH (1982) Sampling bias, gradual extinction patterns, and catastrophes in the fossil record. *Geological Society of America Special Paper* 190: 291–296.

around extinction events, hindering discrimination among the three models of mass extinction.

More powerful statistical methods have been developed to investigate how apparent last occurrences of fossil species may relate to actual times of extinction. These methods involve calculating “confidence intervals” on the time of last sampled occurrence of a species (Figure 4). The basic concept is that the last fossil occurrence of a species that is rarely sampled is a poorer predictor of actual time of extinction than the last occurrence of a species that is densely sampled. Using various models of the density distribution of sampling of a fossil species, probability statements can be made about how far true extinction lies above the last observation of a species.

Magnitudes of Mass Extinction

Questions of abrupt, gradual, or stepwise extinction involve patterns in the fossil record resolved over 10^3 to 10^5 years (encompassing the range from the late Pleistocene extinctions of large mammals to the historical extirpation of species). On larger timescales, general magnitudes of mass extinction can be measured from global fossil data. These data are best for the marine record of animals from continental shelves and seas and fall into roughly three classes of magnitude (Figure 5).

The End-Permian Mass Extinction

This class of magnitude stands alone in its effects on the biota (Erwin, 1993). Compilations of taxa lost indicate that more than 50% of animal families and 80% of genera in the oceans became extinct. Extrapolations of species loss have been attempted, using ecological rarefaction (how many species would be lost given measured declines in genera or families, assuming some distribution of species within higher taxa); results range from 90 to 96% loss of marine species. This loss of marine biodiversity at the end-Permian is unprecedented. Recent work suggests that on land important groups, including insects, tetrapod vertebrates, and plants, also experienced substantial declines in diversity.

Four Other Events of Marine Mass Extinction

This class of magnitude eliminated substantial proportions of marine animals and seem to have had nearly equal magnitudes: the end-Ordovician, Late Devonian, end-Triassic, and end-Cretaceous events. (The occurrence of these events at or near the end of geologic periods reflects the use of faunal change to define intervals of geologic time.) The four events have measured family extinction in the oceans of 15 to 25% and extrapolated species extinctions of 64 to 85%.

Other Intervals of Unusual Amounts of Extinction

This class of magnitude is now termed “extinction events” (Figure 6). These appear in more detailed compilations of the kind Newell made as well as in precise biostratigraphic and paleogeographic analyses. Paleogeographic analyses suggest that many of these third-order events were not global in extent

Figure 3 Apparent gradual extinction at an imaginary sudden extinction event. (a) Actual observed geologic ranges of 20 fossil species. The y-axis is stratigraphic position, in meters, below the Cretaceous/Tertiary boundary. Vertical lines show the total observed ranges of the species and horizontal ticks indicate horizons at which they were actually sampled. The curve at the right, labeled "Diversity," is the sum of the ranges of the species. (b) Resultant ranges if an imaginary catastrophic extinction were imposed at 100 m. Apparent last occurrences of species again are graded below the mass extinction and diversity appears to decline, both as a result of species being irregularly sampled through the geologic interval. (Note that the species in b have been reordered based on their highest geologic occurrence.) Reproduced with permission from Sepkoski Jr. JJ and Koch CF (1996) Evaluating paleontologic data relating to bio-events. In: Walliser OH (ed.) *Global Events and Event Stratigraphy*, pp. 21–34. Berlin: Springer.

Figure 4 Confidence intervals on times of extinction based on the density of sampling of fossil species. The bars represent observed ranges of fossil species with horizontal ticks (including bottom and top of the bars) representing samples of the species. Vertical lines capped by ticks are calculated relative intervals during which there is a 95% probability that extinction actually occurred (thus allowing a 5% probability that real extinction actually occurred higher). The probable position of true extinction is closest to the position of last observation when species are densely sampled, but true extinction can still be expected to be somewhere above the position of last observation. Reproduced from Sepkoski Jr. JJ and Koch CF (1996) Evaluating paleontologic data relating to bio-events. In: Walliser OH (ed.) *Global Events and Event Stratigraphy*, pp. 21–34. Berlin: Springer.

or taxonomic effects, unlike the two previous categories. Examples include the Cambrian bioturbation events, marked by nearly complete extinction of North American trilobites but with uncertain effects in other parts of the world or on other taxa (although some events are recognized in Australia, China, Siberia, and Europe); the lower Toarcian event affecting mollusks in Europe but not around the Pacific basin; and the Pliocene event, again documented for mollusks, in the south temperate Northern Atlantic Ocean and Mediterranean Sea but not evident in the tropics or in the Pacific.

There are extinction events that could be classified at lower ranks. For example, it has been demonstrated that marine animal communities persist on order of 10^6 years during the middle Paleozoic, punctuated by rapid changes in faunal composition (Miller, 1997). This raises the question of Raup (1991a) as to whether extinction events represent a continuum between rare major events and frequent small events (discussed later).

Hypothesis of Periodicity

Given the varying magnitudes and geographic extents of extinction events, one would expect differing forcing agents. With a plethora of forcings acting independently over geologic

time, it would be expected that extinction events would be distributed at random through the fossil record. Thus, it came as a surprise when Fischer and Arthur (1977) and Raup and Sepkoski (1984) observed that extinction events of first through third rank appeared regularly distributed through time. Raup and Sepkoski performed extensive statistical analyses of Newell-type data and concluded there was a strong periodicity of 26 myr for events during the Mesozoic and Cenozoic eras (Figure 7). This suggested some sort of clock-like mechanism behind mass extinction with a periodicity unknown in terrestrial processes. Because one of the periodic events was the end-Cretaceous mass extinction, Raup and Sepkoski speculated that the clocklike mechanism might be extraterrestrial.

This speculation engendered both intriguing hypotheses from astronomers and geologists and critical scrutiny of data and statistical methods from paleontologists, geologists, and statisticians (Raup, 1991b; Sepkoski, 1989). The best-known hypothesis is Nemesis, sometimes called “Shiva;” this is an hypothesized small binary companion to the sun with a large and eccentric orbit that brings it through the Oort Cloud of comets beyond the planets every 26 myr. Nemesis’ gravitational perturbation scatters up to 10^9 comets of which 10^1 to 10^2 might impact the earth, disrupting climate and causing mass extinction.

Nemesis has not been observed, and astronomical models cast doubt on the possibility that a small star could maintain a stable orbit at large distance from the sun through the 4.6 billion-year history of the solar system. Also, there is direct evidence of extraterrestrial impact for only a few of the periodic extinctions, despite intensive investigation: Shocked quartz has been found at several end-Triassic localities, and concentrated iridium, microtektites (annealed globules of impact melt), and a crater have been found in the Late Eocene, although their temporal correspondence to extinctions remains unclear. Searches of this nature are difficult and time consuming, and one should not be surprised if more discoveries are made.

Questions about data and analyses with respect to the hypothesis of periodicity have been largely technical (Sepkoski, 1989). Questions of data concern the veracity of fossil families and genera as indicators of extinction in the geological past and the accuracy of geochronological dating of intervals of extinction. Statistical questions involve problems of analyzing data that are not sampled evenly through time (geologic intervals vary in duration; Figure 7) and problems of significance when performing multiple tests when searching for periodicities of best fit. Some of these questions entered new analytic ground, leading to new kinds of analyses, but not all analytical issues have yet been resolved.

Thus, a nonrandom, periodic distribution of extinction events remains a hypothesis on the table, with neither a clear forcing mechanism nor a definitive analytical test.

The Kill Curve and Self-Organized Criticality

Raup (1991a) treated extinction in the fossil past not as a hierarchy of events but as a continuum, in which the obvious events of large magnitude are rare relative to less obvious

Figure 5 Time distribution of notable extinction events in the marine fossil record, classified as major (“first order”), intermediate (“second order”), and lesser (“third order”) events. Only major and intermediate events are normally referred to as “mass extinctions.” Abbreviations are mostly as in **Figure 1**; l = lower, u = upper. Names refer to stratigraphic intervals (mostly form stages). (?) indicates an event that has not been well documented. Reproduced with permission from Sepkoski Jr. JJ (1992) *Phylogenetic and ecologic patterns in the Phanerozoic history of marine biodiversity*. In: Eldredge N (ed.) *Systematics, Ecology, and the Biodiversity Crisis*, pp. 77–100. New York: Columbia University Press.

events of small magnitude. An analogy is to the historical record of river floods, in which the 1000-year event stands out but is really part of a spectrum with smaller decadal or even yearly events. The 1000-year event does not occur regularly but rather has a chance of 0.001 of occurring during any given year. Raup used a standard function for these kinds of events to analyze probabilities of species extinction of a given magnitude during some duration of geologic time (**Figure 8**): the longer the duration, or “waiting time,” the larger a pulse of extinction that can be expected. The limitation of Raup’s analysis is that it was based on generalized geological intervals, the same as illustrated in **Figures 6** and **7**, and cannot distinguish between sudden events, such as observed at the end of the Cretaceous, and cumulative small events, such as may also have occurred during the last stratigraphic stage of the Cretaceous during the 9 million years prior to the impact-induced mass extinction.

Raup’s analysis was posited on an assumption that external perturbations of varying magnitude caused most extinction through geologic time, and he in fact demonstrated a linear relationship between his empirically based kill curve and the similar curve established for the flux of meteorites of varying magnitude (Raup, 1992). Other approaches have posited extinction to be a result of internal dynamics of the biota over

time. Solé *et al.* (1997), for example, analyzed Phanerozoic time series of extinction and diversity fluctuation to determine if there was evidence of “self-organized criticality.” The prediction was that a power series from fourier transforms of the data would exhibit a linear $1/f^x$ relationship when power was plotted logarithmically against the logarithm of frequency, f . The exponent, x , is expected to be between 1 and 2, which is indeed what was found.

Self-organized criticality refers to systems of interactive components that grow to a degree of complexity that leads to cascades into chaos or collapse. The standard analogy is to a pile of sand onto which one grain is added at a time: As the pile approaches critical size, one more grain can cause a small shuffle of sand while, far less frequently, another grain can cause a major avalanche. The sizes of the avalanches follow the $1/f$ power law. For species, one more new population packed into an interacting community might lead to extinction of a variable number of species if the community were self-critical; usually, extinction numbers would be small, but occasionally there would be a major avalanche of extinction.

There are three criticisms of this argument. First, some mass extinctions are clearly associated with physical disturbances, such as the meteorite impact at the end of the Cretaceous. Second, many other processes can produce $1/f$ power

Figure 6 Extinction intensities for marine animal genera through the Phanerozoic. Intensity is measured as percent extinction ($= 100 \times \text{number of extinctions/observed diversity}$) in geologic intervals averaging about 5.5 myr in duration. Estimated errors of estimate are indicated by error bars (± 1 standard deviation). Significant events are labeled: Tom = Tommotian; uBoto = upper Botomian; Llvi = Llanvirnian; Ashg = Ashgillian (end-Ordovician mass extinction); Ludl = Ludlovian; Frasn = Frasnian (Late Devonian mass extinction); Serp = Serpukhovian; Tatr = Tatarian (end-Permian mass extinction); UNori = upper Norian (= end-Triassic mass extinction); Plie = Pliensbachian; Call = Callovian; Tith = Tithonian; Apti = Aptian; Ceno = Cenomanian; Maas = Maastrichtian (end-Cretaceous mass extinction); uEoc = upper Eocene; mMio = middle Miocene. Reproduced with permission from Sepkoski Jr. JJ (1996) Patterns of Phanerozoic extinctions: A perspective from global databases. In: Walliser OH (ed.) *Global Events and Event Stratigraphy*, pp. 35–52. Berlin: Springer.

Figure 7 Time series for extinction intensity of marine animal genera through the Mesozoic and Cenozoic showing the putative 26 myr periodicity of mass extinction (vertical bars). The abbreviations are as in Figure 6. Extinction intensity here is measured as an average of percent extinction in major taxa that have been standardized to zero means and unit standard deviations. Reproduced with permission from Sepkoski Jr. JJ (1990) The taxonomic structure of periodic extinction. *Geological Society of America Special Paper* 247: 33–44.

Figure 8 Raup's "kill curve" showing the expected extinction of marine species, as a percentage of standing diversity, over intervals of time ("mean waiting time"). During intervals of less than 10^6 years, percent of diversity expected to become extinct is low, but over longer intervals, especially greater than 10^8 years, extinction events of large magnitude become quite probable. The solid line is the best fit curve to fossil data; the dotted curves fall at bounds of uncertainty for empirical data. Reproduced from Raup DM (1991a) A kill curve for Phanerozoic marine species. *Paleobiology* 17: 37–48, with permission from Geoscience World.

laws when analyzed in the way organized self-criticality is; for example, the secular decline in background extinction over time, perhaps induced by changing taxa with different characteristic rates of extinction (Sepkoski, 1984), can cause power series to decline relative to increasing frequency. Finally, there is no independent evidence that species within marine communities, for which data have normally been analyzed, are as interactive as posited.

There still may be some interesting avenues of inquiry to pursue. The state of the biota is not constant, given variations in the earth's climates, changing positions of continents, and varying tectonic events and their effects on environments and the time over which the biota evolves to these varying conditions. A perturbation at one stage of the earth's conditions and the biota's development could have very different effects than an identical perturbation at a different time (Sepkoski, 1989). Thus, an expectation of some chaotic element in the record of extinction cannot be ruled out.

Selectivity of Mass Extinction: Victims and Survivors

An obvious effect of the end-Cretaceous mass extinction is that all (nonavian) dinosaurs disappeared whereas some mammals survived. At other mass extinctions there are also cases of major taxonomic groups disappearing and others surviving. This observation has led to a search for rules as to what makes some kinds of organisms more vulnerable to mass extinction

than others. Patterns that have been found are largely probabilistic, and all seem to have unexplained exceptions:

1. Taxa that have high rates of extinction during times of background extinction suffer disproportionately at mass extinctions. Rates of extinction measured for higher taxa (e.g., classes) during background times tend to be good predictors of magnitudes of extinction at major events. Thus, trilobites, with higher rates of background extinction than articulate brachiopods, suffered more loss at the end-Ordovician, and brachiopods, with higher characteristic rates of extinction than bivalves, suffered greater proportional declines at the end-Permian and even the end-Cretaceous, when brachiopods were relatively marginalized (Sepkoski, 1984). It remains a major question as to why major taxonomic groups have different characteristic rates of extinction during background times and why these rates are conserved over vast stretches of macro-evolutionary history and species turnover.
2. Animals, particularly terrestrial vertebrates, with large body size seem to be particularly prone to extinction. Dinosaurs perished at the end of the Cretaceous whereas many of the small mammals survived; many large mammals and birds that had evolved by the Eocene disappeared during the Eocene-Oligocene transition; and the late to end-Pleistocene extinctions that afflicted all continents other than Africa (and Antarctica) are often referred to as the "Pleistocene large mammal extinctions." Explanations for this selectivity involve (a) lower absolute population numbers of large animals, exposing them to greater chance of all individuals perishing during perturbations and (b) longer gestation times of large mammals, lengthening the time to restoration of pre-perturbation population numbers. Size-selectivity may not apply to marine invertebrates. Jablonski (1996) examined marine mollusks (gastropods and bivalves) for size-selectivity at the end-Cretaceous and found no differential extinction among large-sized species. On the other hand, Fischer and Arthur (1977) argued that marine vertebrate "megacarnivores" were very vulnerable to smaller extinction events.
3. It is often claimed that tropical plants and animals in the fossil past have been more susceptible to extinction than organisms living at higher latitudes. This is based in part on the observation that tropical reef communities disappear at several of the major mass extinctions, including the Late Devonian, end-Permian, and end-Cretaceous events, and millions to tens of millions of years intervene before diverse reefs re-evolve. The pattern for level bottom marine communities is not so clear: Jablonski and Raup (1995) analyzed the biogeography of bivalve extinction at the end of the Cretaceous and found no difference in extinction between tropical and temperate genera that were not associated with reefs.
4. Taxa with restricted geographic ranges appear to have been more prone to extinction than widespread taxa. Jablonski (1995) documented this for Late Cretaceous molluscan species during normal times of background extinction. At the end of the Cretaceous, however, the geographic range of individual species did not seem to be a factor, with

widespread species suffering as much extinction as restricted species. At the rank of the genus, however, genera with geographically dispersed species tended to survive preferentially relative to genera with species restricted to one or a few biogeographic provinces. Similar results have been obtained for Cambrian trilobites at various extinction events.

5. Environment seems to have played only a minor role in selectivity of extinction among marine animals at mass extinctions. Rates of extinction among Paleozoic marine animals tended to increase toward shallower waters during background times but to be equal across continental shelves at mass extinctions. There is some suggestion, however, that deep-water animals fared better: Marine shelves seem to have been repopulated by descendants of deep-water trilobites after Cambrian extinction events; shelf communities contained disproportionate numbers of deep-water sponges and corals after the Late Devonian mass extinction (McGhee, 1996); and descendants of mollusks typical of low-oxygen deep-water communities of the late Paleozoic are common after the end-Permian mass extinction (Erwin, 1993).

These reports of taxonomic selectivity at mass extinctions are largely confined to analyses around a few events of extinction, and much larger comparative studies need to be conducted across all mass extinctions for both marine and terrestrial organisms. However, if there are consistent probabilistic biases in terms of the properties of species and higher taxa that survive mass extinctions, then extinction events on frequencies of 2.6×10^7 years, eliminating 30 to 90% of the biota, could be a major factor in the history of life.

Recoveries from Mass Extinctions

Global data on mass extinctions exhibit not only the geologically rapid declines of the biota at mass extinctions but also subsequent recoveries of biodiversity in the aftermaths. With modern data, these recoveries are seen to encompass longer intervals of time than the extinction events, ranging up to about 5 myr for third-order extinction events to around 10 to 15 myr for second-order mass extinctions; recovery from the great end-Permian mass extinction took even longer but was interrupted by the end-Triassic event, some 30 myr later.

On long geologic timescales, recoveries from mass extinctions follow simple patterns expected for a diversifying biota. At more detailed scales, there is great complexity, with some patterns repeated after every mass extinction.

Large-Scale Rebound of Diversity

To a first approximation, diversification in the oceans can be described as a system with equilibrium constraints imposed by limitations of resources and their utilization (Sepkoski, 1984, 1992). This is most obvious in the long plateau of diversity during the Paleozoic era, spanning approximately one-quarter billion years. This interval witnessed two second-order mass extinctions, the end-Ordovician and Late Devonian. Significantly, after each, animal diversity rebounded to previous,

unperturbed levels and then continued the Paleozoic plateau (Figure 1b). Also, the rate of rediversification after these mass extinctions was approximately the same as during the Ordovician radiations that established the Paleozoic plateau of global marine diversity.

Such a system can be modeled if it is assumed that Paleozoic animals were constrained by an equilibrium diversity, conditioned on the environment and the way these animals subdivided resources (Figure 9). The simplest mathematical description of diversification is a logistic model, assuming decreasing rates of origination as diversity increases. A mass extinction is a perturbation to the environment that increases extinction rates (Figure 9b). Following the perturbation, when extinction rates return to background levels, taxa rediversify to the normative level (Figure 9c).

Patterns are more complex through the quarter-billion years after the Paleozoic era, as diversity in the oceans generally increased. The increase reflects expansion of the modern marine fauna, which may have subdivided resources in ways different from the fauna of the Paleozoic era. Nonetheless, rebounds after mass extinctions during the Mesozoic and Cenozoic eras were much more rapid than the long-term increase in marine diversity when measured over millions of years and were congruent with initial rates of diversification of the taxonomic groups involved (cf. Miller and Sepkoski, 1989).

Delayed Diversification

When rebounds from mass extinction are analyzed at finer timescales, many complications become apparent (Erwin, 1998). One is delayed recovery: rediversification does not commence immediately after perturbations. For example, there are only slow rates of rediversification for 10^5 years after the end-Cretaceous event among planktonic foraminifers (actually, fast at first and then slow for some four myr; D'Hondt *et al.*, 1996), benthic mollusks (Jablonski, 1998), and terrestrial mammals (Maas and Krause, 1994). Recovery seems to be delayed for nearly 5 myr after the much larger end-Permian event, with only depauperate faunas in the oceans and on land (Erwin, 1998).

Explanations for this pattern have varied. Some workers have suggested that the extended post-extinction intervals of low diversity reflect lingering effects of the external perturbation—that is, continued environmental stress or instability. Others have hypothesized that substantial amounts of time are required for the evolution of new species that can reestablish normal ecosystem function which, in turn, can support high diversity. An example is the evolution of planktonic microherbivores after the end-Cretaceous mass extinction (D'Hondt *et al.*, 1998). The delayed interval of recovery after the severe end-Permian event could even be conceived as a long lag in a logistic system after diversity had been reduced by an order of magnitude.

“Disaster Species” and “Lazarus Taxa”

A feature that appears consistent during early phases of recovery from mass extinction is the appearance of “disaster

Figure 9 Observed and modeled loss and recovery of diversity around a mass extinction. (a) Observed numbers of genera through the Ordovician and Silurian periods, illustrating the major decline in diversity at the end of the Ordovician and subsequent recovery during the Silurian. Note that the rate of recovery is not very different from the rate of radiation during the Ordovician (cf. Figure 1) and that diversity during the Silurian recovers to the same level as during the late Ordovician. (b) Structure of a logistic model to describe diversification, mass extinction, and recovery. It is assumed that diversity increases multiplicatively and that per capita rates of origination decrease with increasing diversity, leading to sigmoidal growth of diversification. A mass extinction is a temporary steepening of the extinction function (or, alternatively, increasing of its elevation). $\hat{D}$ signifies the diversity at which origination rate equals extinction rate during normal times and diversity no longer grows. (c) A solution to the logistic model using rates measured from Ordovician marine animals, with a perturbation (arrow) applied at a model time corresponding to the observed end-Ordovician mass extinction. Diversity declines precipitously when extinction rate is increased, but then rebounds when extinction is returned to normal. Diversity in the model solution rebounds at the same rate as the Ordovician radiations and equilibrates at the same level as previously. Reproduced with permission from Sepkoski Jr. JJ (1992) Phylogenetic and ecologic patterns in the Phanerozoic history of marine biodiversity. In: Eldredge N (ed.) *Systematics, Ecology, and the Biodiversity Crisis*, pp. 77–100. New York: Columbia University Press.

species.” These are remarkably abundant and geographically widespread species that appear in the waning stages or aftermaths of mass extinctions. Examples include the small

foraminifer, *Guembelitra*, that spread out from marginal environments to form nearly monospecific assemblages immediately after the end-Cretaceous extinction and the terrestrial “fern spike” observed at the same time on land. Another example is the terrestrial synapsid (“mammal-like reptile”), *Lystrosaurus*, that produced monospecific assemblages in Gondwanaland following the end-Permian mass extinction.

Disaster species are characterized by not only great abundance in fossil deposits but also short geologic durations. Marine disaster species seem to flourish for around 10^5 years and then disappear, often to be replaced by another “disaster species” with similarly short duration. This appears like an evolutionary “boom and bust” cycle. Thus, the earliest Tertiary foraminifer, *Guembelitra*, declined and was replaced in dominance by a succession of bursts of *Paravularugoglobigerina*, “*Eoglobigerina*,” and finally *Woodringina* over timescales of 10^5 years as the planktonic ecosystem seemed to regain stability.

Perhaps the antithesis of disaster species are “Lazarus taxa.” These are lineages that disappear around mass extinctions—seemingly to have died—only to reappear in the fossil record some 10^6 to 10^7 years later (Erwin, 1998; Jablonski, 1986). These can be conspicuous but usually never dominant members of the biota prior to a mass extinction. Presumably, these taxa survived in some environmental or geographical refugium until the ecosystem regained sufficient function so that their dispersal—and recovery of sufficient abundance to be encountered by paleontologists—was possible.

The Modern Biodiversity Crisis

The collapses of ecosystems in the fossil past can inform thinking and actions with respect to the contemporary loss of biodiversity. The fossil record is incompletely known, but the data seem little worse than estimates of living biodiversity and current rates of species extinction. Estimates of modern global biodiversity range over more than an order of magnitude, from 5 to 100×10^6 species. Estimates of present-day loss of species range over nearly two orders of magnitude, from 5 to 150 species extinction *per day*. Most of these extinctions are terrestrial animals (largely insects), whereas the best data from the fossil record are for marine species. Still, in the geologic past, mass extinctions appear to have occurred largely contemporaneously both on land and in the seas (except for the end-Pleistocene event), so some simple calculations can be made.

If a median contemporary extinction rate of 41 species per day is assumed and species attrition is treated as a negative exponential, then it would take only about 16,000 years for 96% of the modern biota to become extinct (Sepkoski, 1997). This is a long time by human standards, but it is beyond the limits of geologic resolution at 250 Ma (the end-Permian), the only other time when 96% of Earth’s biota disappeared.

This discussion has been largely in terms of fossil diversity. Another variable that can be measured in the geologic record is ratios of stable carbon isotopes. Because organisms tend to utilize ^{12}C in slight bias over the heavier ^{13}C , the ratio of the two isotopes preserved in the rock record can indicate, among other things, the activity of primary producers. For example, after the end of the Cretaceous, there was no difference in isotopic ratios of carbon in the skeletons of surface planktonic

foraminifers and deep-sea benthic foraminifers. This indicates that organic carbon stopped sinking to the deep ocean. This change must have resulted from either (a) a major decline in oceanic productivity or (b) a major collapse of community structure in marine producers or consumers (D'Hondt *et al.*, 1998).

Summary

Exploration of the fossil record has demonstrated that the earth's biota is fragile at timescales of 10^7 years, suffering numerous declines in diversity. The magnitudes of these declines have been variable, but at least five times in the last 500 myr animal diversity was reduced by more than 50%, with the most severe event, at the end of the Permian, eliminating more than 90% of animal diversity. Recoveries from these events have been slower than the mass extinctions, often taking 5 to 10 myr or more. Although the long-term rebounds of biodiversity are predictable, the detailed patterns of recovery are complex, involving outbreaks of disaster species and considerable ecological instability over timescales of 10^5 to 10^6 years. Current rates of species extinction could eliminate as many species as seen in past mass extinctions in a geologically short interval, and biotic recovery could be long and unpredictable.

Glossary

Mass extinction A rapid loss of a large fraction of biodiversity on timescales of 10^0 – 10^6 years, generally involving a variety of unrelated groups.

Supercontinent The amalgamation of many continental masses into a single mass through continental drift. The

supercontinent of Pangaea (from 300 to approximately 190 million years ago (Ma)) included most continental areas other than those that comprise east Asia.

Introduction

The 3.6-billion-year history of life on Earth has been punctuated by numerous extinction events, but much of that history is poorly known due to a patchy and incomplete rock and fossil record. Only the record of the past 600 million years is sufficiently well preserved to provide an adequate archive of these biotic crises. Five great mass extinctions punctuate this recent slice of Earth history, which spans most of the evolution of animals and multicellular plants. Additionally, there are many smaller biotic crises, but not all of these are well studied.

Great Mass Extinctions

The five most severe intervals of biotic crisis occurred during the Late Ordovician Period, the Late Devonian, the Late Permian, the Late Triassic, and at the end of the Cretaceous (Figure 1). A variety of different causes have been invoked, from climate change (both warming and cooling) to the impact of extraterrestrial objects, but despite numerous attempts to find a common mechanism for these events no single factor appears to have caused all events. One of the challenges of studying these ancient events is that the rock and fossil records are both imperfect archives, with gaps and missing information. This is one reason that estimates of past biodiversity are often compiled at the taxonomic resolution of families (Figure 1) or genera (Figure 2), rather than species. As new fossiliferous locations are discovered or studied in more detail, and as new methods of coping with biases in the rock and fossil records are developed, our knowledge of these events improves and estimates of extinction rates are revised. Technological advances, especially in the fields of geochemistry, geochronology, and microscopy are also providing important new information concerning the timing of these events and their associated environmental changes.

Late Ordovician

The first of the five great mass extinctions occurred during the Late Ordovician, approximately 445 million years ago (Ma).

At that time there were few, if any, organisms on land, and this crisis was confined to marine groups. Detailed studies have revealed the presence of two linked, but clearly separate, extinction events: one at the very end of the Ordovician and another 1–2 million years earlier. Overall, approximately 25% of all families disappeared, with extinction of approximately 49% of all genera in the first event and 44% in the second event. Despite the apparent magnitude of the extinction, it had few lasting ecological effects: with some minor exceptions, Silurian faunas look much like Ordovician ones, with similar groups of organisms occupying similar niches.

Graptolites, a group of colonial, floating (planktonic) marine organisms, were commonly found on the outer shelves and were almost completely eliminated by this extinction, with only a few species surviving. Other planktonic groups and swimming (nektonic) groups, such as conodonts and nautiloids, all appear to have suffered considerable extinction. On the seafloor, the articulate brachiopods were one of the major components of Ordovician seafloor (benthic) ecosystems, and approximately 83% of brachiopod genera became extinct, primarily during the first of the two events. A brachiopod genus, *Hirnantia*, and its associated fauna, appeared in many areas in the aftermath of the first extinction event. At any particular locality, fewer than 10 species are typically present in total and all appear to be adapted to cold water. This 'Hirnantian fauna' reached equatorial latitudes during this interval, but was wiped out by the second extinction event. Trilobites display a similar pattern of extinction followed by the spread of a low diversity, broadly distributed group between the extinctions; however, the second extinction appears to be more significant than the first. Trilobites living in deeper water suffered greater extinctions than those occupying shallow-water habitats. Bivalves and echinoderms also experienced considerable extinction, whereas bryozoans, a colonial group of filter feeders, were not affected as severely. Approximately 70% of rugose corals disappeared, but they recovered quickly so the extinction did not have a major impact. In fact, this is the only major mass extinction that did not trigger an extensive turnover in reef communities.

The causes of the Late Ordovician mass extinction appear to be linked to global climate change and its associated environmental impacts. Warm temperatures characterized the

Figure 1 Past diversity of marine families. Early Ordovician as the Earth was experiencing a greenhouse climate, with carbon dioxide levels and temperatures much higher than those of the present day. Through the Early Ordovician there is evidence that climate gradually cooled, and from the Middle Ordovician tropical sea surface temperatures were much more similar to those of the present day (Trotter *et al.*, 2008). Global climate remained fairly equable through the Middle and into the Late Ordovician, but sometime in the Katian (the penultimate stage of the Ordovician, about 450 Ma) temperatures begin to fluctuate. It appears that a tipping point was reached toward the end of the Katian and global temperatures plummeted by some 8 °C through the early part of the Hirnantian Stage, plunging the world into the grips of a global icehouse (Finnegan *et al.*, 2011). As climate cooled ice sheets would have expanded, causing sea level to drop, eventually exposing the continental shelves. The first extinction event, which eliminated nearly half of all genera, is intimately linked to cooling and sea level fall at this time, as organisms succumbed to pressures such as lowered temperatures, changes in ocean circulation and reduced space on shallow marine shelves.

The reason for the climatic instability and onset of cooling are still unresolved. Plate tectonics might have had an influence as a large continental landmass moved close to the South

Figure 2 The past diversity of marine genera. The line shows the total number of marine genera recorded in the fossil record through the geologic periods of the Phanerozoic. The circles correspond to the five major mass extinctions: (1) Late Ordovician; (2) Late Devonian; (3) Late Permian; (4) Late Triassic; and (5) end-Cretaceous. Pole during the Ordovician. Elsewhere, the chemical weathering of mountain belts formed by plate collisions may have helped reduce the level of carbon dioxide in the atmosphere. Some evidence suggests that ice sheets may have been present, at least transiently, as early as the Middle Ordovician, implying a lengthy and complex interval of climate change preceding the onset of catastrophic cooling (Finnegan *et al.*, 2011). In the wake of the first extinction event, as global temperatures and sea level fell, the low-diversity, cool-water Hirnantian fauna became widespread. Around the middle of the Hirnantian stage, global cooling ceased and temperatures began to rise once more through the latter part of the Hirnantian. As the Earth emerged from global icehouse conditions and ice-sheets retreated once more, sea level and ocean temperatures would have increased. The warm, rising seas, associated with the spread of low oxygen, or anoxic, conditions, led to the second episode of extinction at the end of the Hirnantian.

The sea-level fall of the Late Ordovician glaciation prevented the deposition of shallow marine rocks in many areas, as the shelves became exposed. This complicates the scientific analysis of biodiversity changes during this interval. Do certain species disappear because of real biological extinction, or simply because the types of rocks that preserve their fossils are no longer present?

This is a problem that affects the analysis of all past extinction events to a greater or lesser extent, especially further back in time when the global rock record is generally less complete (Smith, 2007). Although rocks recording the Late Ordovician crisis are common in Europe and China, for example, deposits of that age in North America are limited to a few places in central Nevada, USA, and Anticosti Island,

Canada. The Nevada sections record a diversity of environments within a small region, however, which is rarely the case elsewhere and which allows the extinctions to be tracked between different environments (Finney *et al.*, 1999).

The potential problems of biases in the rock record and inadequate or patchy sampling have led some scientists to question whether the trends in Phanerozoic diversity identified by Sepkoski (Figure 1) reflect a true picture of past biodiversity, or merely reflect the vagaries of the fossil record. A National Science Foundation initiative to document fossil diversity more completely and thoroughly than previous attempts have been able to manage – known as the Paleobiology Database project – has resulted in a revised view of the history of life on Earth that attempts to take into account biases in sampling. While the ‘Big 5’ extinctions still coincide with reductions in global diversity (Figure 3), some of the details of the timing, magnitude, and duration of the various peaks and troughs are different. This alternative view is not accepted by all scientists, and the Paleobiology Database is far from complete, but the approach demonstrates how biases that might be affecting our understanding of the history of life on Earth could potentially be filtered out.

Figure 3 The past diversity of marine genera, corrected for sampling bias. The uppermost line shows the number of marine genera recorded in the fossil record through the geologic periods of the Phanerozoic and uppermost Neoproterozoic. Late Devonian

The Late Devonian Period records a number of closely-spaced, apparent biotic crises of varying magnitude, which together create a substantial decrease in diversity at this time (Figure 1). These biotic crises have been recognized since the 1870s, but the rapidity of these events remains unclear. For the Givetian and Frasnian Stages of the Late Devonian, Sepkoski (1996) records a 57% extinction of marine genera (47% for filtered data) and approximately 22% extinction of marine families. The most significant events of the Devonian appear to have occurred at the end of the Givetian Stage (the ‘Taghanic event’, some 385 Ma), at the end of the Frasnian (the ‘Kellwasser event’, 375 Ma), and finally at the end of the Famennian (the ‘Hangenberg event’, 360 Ma). Terrestrial plants had evolved and experienced their first major biotic crisis during this interval as well, although the available data are somewhat patchy (McGhee, 1996; Hallam and Wignall, 1997). Although these events show some similarities with each other, they evidently represent separate events separated by intervals of biotic recovery.

Middle Devonian shallow seas were dominated by extensive reef ecosystems, extending from 45° to 50° south of the equator to perhaps 60° north. Major Devonian reef complexes are known from Australia, western North America, Russia, and Europe, with areal extents often many times that of the present day Great Barrier Reef. These reefs were dominated by rugose and tabulate corals (the major reef builders of the Paleozoic), stromatoporoids (a type of calcified sponge), in addition to reef dwellers such as brachiopods, bryozoans, and large foraminifera. The extinctions suffered by these groups during the Late Devonian resulted in collapse and near elimination of reef ecosystems. The end-Givetian Taghanic event witnessed the most severe extinction for the corals and reef dwellers. At least six families of brachiopods, 47% of stromatoporoid genera, and 50% of coral genera disappeared at this time, and the bryozoans suffered their largest biotic crisis. The few surviving tabulates, colonial rugosans, and stromatoporoids regrouped during the early Frasnian, forming low diversity, but regionally extensive, reefs that reached peak sizes and areal extents by the Middle Frasnian. Reefs then declined through the latest Frasnian becoming very isolated and geographically restricted just before their final extinction immediately preceding the Frasnian/Famennian boundary (Copper, 2002). Alongside the decline in coral reefs, McGhee (1996) indicates that 75% of brachiopod genera disappeared during the Frasnian. Brachiopods recovered quickly during the Famennian, but corals and stromatoporoids did not. No coral reefs are known from the Famennian, and just a few isolated examples of stromatoporoid patch reef are all that remain of the former dominance of these metazoan reef builders. Most Famennian reefs were constructed by microbial organisms, and stromatoporoids were completely extinct by the end of the Devonian (Copper, 2002).

Trilobites, although much reduced in diversity from the Cambrian and Ordovician, were still important during the Devonian. Eight orders and 13 families are known from the Givetian, but only a single family and eight genera survived to the Famennian. Although there is elevated extinction from the Givetian through the Frasnian, the only discrete crisis

occurred during the end-Frasnian Kellwasser event when numerous important groups disappeared. Deep-water and some shallow-water trilobites diversified immediately after the extinction during the Famennian, but trilobites suffered considerable extinction again at the end-Famennian and never regained their previous diversity. Two other arthropod groups, the eurypterids (sea scorpions) and the ostracods, were also members of Devonian marine communities. Eurypterids were relatively rare, large predators and their diversity appears to be declining throughout the interval, although several families became extinct during the last two stages of the Devonian. Ostracods were more common, comprising both benthic and pelagic forms, and suffered considerable extinction during the Kellwasser event. Some 75% of benthic ostracods disappeared then, with genera tolerant of low-oxygen conditions showing greater survival.

Ammonoids, the coiled cephalopods that were distant cousins of the modern chambered *Nautilus*, almost disappeared, with an estimated 88% species extinction. Ammonoids display a boom-and-bust pattern throughout their history, and this includes massive extinctions during the Taghanic event, in which only two genera survived, and the Kellwasser event, with only a few surviving genera, mostly from deeper water habitats. Famennian ammonoids diversified considerably, but only a single family, and perhaps a single genus, survived the Hangenberg event at the end of the Devonian. Nautiloids, the other major group of fossilizable cephalopods, suffered minor perturbation during the Kellwasser event, but suffered perhaps their greatest crisis during the Hangenberg event when 11 of 19 families disappeared. In contrast to the cephalopods, other molluscs such as bivalves and gastropods suffered only minor losses in diversity.

The Devonian is sometimes known as “the Age of Fishes” due to the enormous diversity of fish during that period. Most fish groups did poorly during the Late Devonian, which marked the complete extinction of the jawless, armored forms as all nine of their families disappeared. More advanced fish and other vertebrate groups suffered as well during both the Kellwasser and Hangenberg crises, with generic losses of 19% and 32% at each event, respectively. The latter crisis led to a major restructuring of vertebrate communities with the diversification of previously less common groups such as sharks and tetrapods that dominate marine and nonmarine habitats at the present day (Sallan and Coates, 2010).

What patterns of ecological selectivity are apparent from the variations in extinction intensity among different groups? Often, patterns of differential extinction are among the best clues to the causes of mass extinctions and other biotic crises. The patterns of change are complex, with long-term decline in many groups as well as during the discrete Taghanic, Kellwasser, and Hangenberg events. The first of the three biotic crises primarily affected shallow-water benthic groups. The Kellwasser is the best known of the three events (McGhee, 1996). Warm-water groups, particularly brachiopods and reef forms, suffered the greatest extinction, whereas groups adapted to high latitudes and colder waters seem to have fared better. Most swimming groups either became extinct or declined greatly in diversity. Whether the Hangenberg crisis qualifies as a mass extinction is unclear. Many swimming groups, including placoderm fish, nautiloids,

and ammonoids, as well as trilobites and stromatoporoids experienced considerable extinction (Hallam and Wignall, 1997).

Extraterrestrial impact, sea-level fluctuations with attendant spread of anoxic waters, and climatic changes such as global cooling are among the more prominent suggested causes of the biotic crisis (McGhee, 1996). The evidence for impact would include demonstration that extinctions are rapid and virtually simultaneous; a coincident enrichment of iridium, which is rare on Earth but common in extraterrestrial objects; mechanical indications of impact including shocked quartz; fused glass from the impact site; and a crater of the correct age. Although evidence of impact is present in Late Devonian rocks, including the 52-km Siljan crater in Sweden and heightened levels of iridium, these are not closely associated with extinction horizons.

Evidence in support of global cooling includes the heightened survival of cold-water groups, the presence of glacial sediments in Brazil and the eastern USA, and the rapid sea-level fluctuations, reminiscent of Pleistocene glacially induced fluctuations (Copper, 1998). While enhanced survival of cold-water taxa can also be interpreted as survival of deep-water forms, McGhee (1996) concludes that global cooling best explains the pattern of extinction and survival, although he argues that the rapidity of the extinctions perhaps indicates that glaciation is not an adequate explanation.

A number of alternative scenarios have been proposed, most of which invoke sea level, shifts in the carbon cycle, and spread of oxygen-poor waters (Hallam and Wignall, 1997). The scenarios differ in the triggering mechanism, which ranges from rapid glaciations to oceanic volcanism and the effects of increased flux of nutrients to the oceans caused by the first development of land plants. Evidence for warming and anoxia has been questioned, with Copper (1998) noting that many of the atrypid brachiopods adapted to low-oxygen environments became extinct while other brachiopods from the same communities survived. Investigations of these events continue, but currently there does not appear to be sufficient evidence to provide definitive tests of the various competing models for the causes of this extinction. The most reasonable explanation, however, appears to involve a multitude of interacting causes rather than a single critical cause.

Late Permian

The most severe mass extinction event of the Phanerozoic occurred just prior to the very end of the Permian Period, in the late Changhsingian (252 Ma), and caused the most pervasive reorganization of marine communities since the beginning of the Paleozoic (Erwin, 1993). All subsequent marine communities, right down to the present day, reflect the heritage of this event. Extinctions on land were no less severe, and include widespread disruption of plant communities, extinction of most vertebrate taxa, and the only mass extinction suffered by insects. This unparalleled upheaval in the evolutionary history of animals and plants was preceded by a smaller magnitude episode of marine extinction at the end of the Guadalupian, some 8 million years earlier. In some former studies this end-Guadalupian crisis was treated as part of the

'Late Permian' mass extinction event, although detailed analyses from the 1990s clearly show them to be separate and distinct.

A number of major groups of organisms that had dominated the oceans for the previous 250 million years or more disappeared completely during the Late Permian. Some of those, such as the trilobites, had already dwindled to a few species and had long since passed their peak. Others, such as the rugose and tabulate corals, were common and widespread yet still vanished completely. Reef-building organisms, such as sponges, corals, and algae, are common in Changhsingian rocks in many areas, for example, Sichuan Province, China, but after the extinction event metazoan reefs are not recorded again until the Middle Triassic. Scleractinian corals – major reef-builders during the Triassic as they are at the present day – diversified from some unknown, perhaps soft-bodied, extinction survivor to fill the niches that were vacated by the extinction of the Permian reef builders. Brachiopods are perhaps the most diagnostic group of Paleozoic marine organisms, but lost some 90% of their genera during the Late Permian event. Two echinoderm classes that were diverse and abundant during the Paleozoic, the echinoids and crinoids, were saved from complete extinction by the survival of just one or two genera. The morphology of all modern sea urchins is largely inherited from the one surviving genus *Miocidaris*. Our understanding of the impact of the Late Permian extinction on the other echinoderm classes, namely the brittle stars, sea stars, and sea cucumbers, is impeded by a very poor quality fossil record for those groups during the crucial interval. Initial diversification of modern starfish appears to have taken place during the Triassic, perhaps indicating that a single genus survived the extinction, whereas it appears that no major groups of sea cucumbers were lost during the Late Permian, implying the survival of a number of genera. Molluscs dominate most post-Paleozoic marine shelf communities, from the earliest Triassic to the present day, and it is not surprising that they suffered lower extinction rates than many other organisms, although they still lost significant numbers of taxa. Gastropods, for example, experienced approximately 75% extinction at the generic level, and bivalves lost 60% of their genera. Within the cephalopods, which lost 75% of genera overall, the ammonoids, as usual, fared particularly badly. Marine communities in the immediate aftermath were dominated by a handful of bivalve genera, with a few gastropods and inarticulate brachiopods, and show remarkably little variation worldwide.

Extensive biotic crises occurred on land as well. Clearly, any proposed cause that affects the oceans to the exclusion of land is ruled out. Twenty-two orders of insects had appeared by the end of the Permian, and nine became extinct and another 10 suffered serious diversity declines. This is the only mass extinction ever suffered by insects. Many of the groups that disappeared could not fold their wings back over their body (as do flies and butterflies) but rather held them straight out to the side; dragonflies are a relic of these Permian groups. In contrast to studies in the 1980s, which suggested that plants experienced relatively little extinction, recent work has revealed massive perturbations, including the loss of high-latitude gymnosperm forests. Terrestrial ecosystems supported a great variety of vertebrates, including large herbivores and

saber-toothed carnivores, but approximately 78% of tetrapod families became extinct at this time. Fossil spores and pollen preserved in shallow marine rocks show that ecological disruption on land occurred at the same time as extinction in the seas. Efforts to accurately date the extinctions have been ongoing since the late 1990s (Bowring *et al.*, 1998) and it seems likely that most extinctions occurred in a period of some 20,000 years or less (Twitchett *et al.*, 2001).

Almost every conceivable cause has, at one time or another and with varying degrees of support, been suggested for the Late Permian mass extinction event. Certainly, the cause was terrestrial in origin, as despite decades of investigation and numerous published studies since the early 1980s, none of the evidence put forward for extraterrestrial impact has ever held up to detailed scrutiny or analysis. Some hypotheses have become obsolete as more precise measurements of the timing and duration of the crisis have been made. Thus, the once-favored explanation that the extinctions were the direct result of the assembly of the supercontinent Pangaea can be rejected because the assembly was complete at least 20 million years before the Late Permian, and the crisis itself was far too rapid to be explained by the slow dance of the continents. Another view, held by several generations of workers, was that sea level fall was responsible. This hypothesis was based on the observation that in many places, especially in North America, marine strata of latest Permian and earliest Triassic age are absent, and the Permian/Triassic boundary is marked by an unconformity. High-resolution studies in the 1990s that focused on areas where the rock record is much more complete, such as northern Italy and Svalbard, demonstrated that although a significant sea-level fall did indeed occur in the Changhsingian stage of the latest Permian, it was associated with few apparent extinctions, and the mass extinction interval actually occurs during the subsequent sea level rise.

The hypothesis that global cooling and widespread glaciations were the ultimate cause still has low levels of support, despite the facts that no glacial deposits of the correct age have been identified anywhere on the planet and, as noted, the extinctions are demonstrably not associated with falling sea level. There is much more evidence to support the alternative view that the Late Permian extinction event was associated with an episode of catastrophic global warming.

The overall climatic trend through the Permian is one of increasing warmth. During the late Carboniferous and Early Permian, the Earth was in the grip of a major icehouse, with continental scale ice-sheets covering much of the southern hemisphere land surface. Gradually, as atmospheric carbon dioxide levels rose through the Permian, the icesheets disappeared so that by the Late Permian all evidence of glacial deposits has vanished, replaced by widespread evidence for hot desert conditions at lower latitudes and lush, dense forests at higher latitudes. Computer-generated climate simulations support the rock record evidence that the Late Permian was a warm interval in the planet's history. Then, in the final stage of the Permian, there is a further increase in atmospheric carbon dioxide levels, recorded in changes in the density of pores (stomata) on fossil leaves and in the chemistry of fossil soils. This sudden spike in greenhouse gases would have fueled additional global warming, which would have led to increased temperatures, sea level rise, and changes to atmospheric and

ocean circulation with catastrophic consequences for the terrestrial and marine biota. Evidence of rising temperature at this time was first gathered in the late 1980s from chemical analyses of shallow water, tropical limestones, which suggested an increase of 5–6 °C through the marine extinction event. More accurate measurements 20 years later on better preserved, tropical, shallow marine brachiopod shells gave estimates that were much higher: a temperature increase through the extinction of perhaps 8–10 °C (Kearsey *et al.*, 2009).

What caused this catastrophic Late Permian greenhouse? It is probably no coincidence that the Late Permian also witnessed the formation of the largest volcanic province to have erupted on land during the Phanerozoic. The eruptions covered an area of some 5 million square kilometers of present-day western Siberia, Russia, with layer on layer of basaltic lava to a depth of more than 3 km in some places. The total volume of extrusive and shallow intrusive igneous rocks is estimated at between 2 and 4 million cubic kilometers (Saunders and Reichow, 2009). Within error, the ages of most lava flows span the extinction event. These eruptions would have released large amounts of carbon dioxide, which gradually built up in the atmosphere, possibly further enhanced by the presence of underlying coal-rich rocks that would have been cooked as the molten magma passed through on its way to the surface.

Rising temperatures alone would probably have caused extinction of some groups of animals and plants. Warming would also cause other environmental changes that would have disrupted the food supply, nutrient supply or life cycle of organisms. Extreme seasonality, changes in rainfall patterns and expansion of climatic belts would have affected terrestrial plants and animals. In many areas it appears that lush gymnosperm forests gave way to sparse shrubby vegetation. Seasonal rainfall and reduced vegetation cover resulted in a change from meandering to braided river systems, as shown by the sudden appearance in the rock record of thick conglomerates and pebble beds in most localities. Erosion of the landscape was enhanced by elevated CO₂ levels, and the rivers must have discharged vast plumes of brown, muddy water into the coastal seas causing an increased flux of land-derived nutrients into shallow marine ecosystems. Marine rocks in the immediate aftermath of the extinction record this increased sedimentation rate in thick, muddy rock sequences (Algeo and Twitchett, 2010). Aquatic ecosystems would have suffered increased turbidity, harmful to many organisms, and marine shelves would have experienced frequent anoxic episodes as the enhanced nutrient flux would have fueled blooms of phytoplankton.

Beyond the shallow shelves, the rest of the ocean was also severely impacted. As global warming tends to cause greater temperature increase in polar regions, the thermal gradient between the tropics and the poles would become much reduced. Normally, this gradient drives the thermohaline circulation that provides a constant supply of cooler, oxygen- and nutrient-rich waters to the deep ocean. As warming proceeded, circulation would become less vigorous and many parts of the ocean would become starved of oxygen and nutrients. Global ocean productivity levels would fall as upwelling zones became less productive. Evidence of anoxic

deep oceans has been documented from the rock record of Japan. Fossilized molecules derived from green sulfur bacteria, which need both light and hydrogen sulfide, are present in many marine rocks in the immediate aftermath of the extinction, showing that at times the oceans were anoxic from the seafloor up to the photic zone.

Some regions evidently fared better than others, and patterns of recovery vary between regions. At least some seamounts and offshore highs, such as those in Oman documented by Krystyn *et al.* (2003), were not affected by increased sedimentation or anoxic conditions and record a relative rapid ecological recovery. Although much work still needs to be done, it appears that the Siberian Trap eruptions were relatively short lived and within a million years or so atmospheric CO₂ levels declined to pre-extinction levels. Most tropical ecosystems on land and in the oceans did not fully recover until late in the Early Triassic, some 5 million years after the extinction.

Late Triassic

The Late Triassic biotic crisis records the second smallest extinction magnitude of the 'Big 5' events, but is ranked third in terms of its ecological impact (McGhee *et al.*, 2004). Although the least studied of the major events, it has attracted an increasing amount of scientific attention since the start of the twenty-first century due to present-day climate concerns: the Late Triassic event is associated with clear evidence of global warming and is the most severe crisis to have affected groups that make up the modern marine fauna (Figures 1 and 3).

Sepkoski's (1996) data show that 53% of all marine genera became extinct (40% when the data are filtered) and 22% of marine families. Among marine groups, Sepkoski's database shows significant extinctions among ammonoids, bivalves, gastropods, and brachiopods. Ammonoids experienced a boom-and-bust pattern throughout their history, and this event marks one of their largest crises. The group was quite diverse during the latest Triassic, but at least six superfamilies became extinct near the boundary, followed by a rapid rediversification in the Early Jurassic. Some estimates suggest that only a single ammonite genus survived the crisis. Although no family-level extinctions occurred among bivalves, approximately half the genera disappeared and turnover at the species level was particularly high. Endemic genera and those in deep offshore facies or associated with reefs appear to have experienced greatest extinction. Conodonts, a group of phosphatic microfossils formed by simple chordates, had survived all previous mass extinctions, but finally became extinct at the end of the Triassic. Extinction of foraminifera and ostracods was relatively minor. Reefs dominated by scleractinian corals first appear in the Middle Triassic and become prominent in the Carnian. These corals, associated sponges, and other reef taxa suffer a sharp reduction in diversity during this episode, followed by an interval during which reefs are absent.

Some terrestrial groups experienced extinction at this time as well, although disruption was less severe than during the Late Permian or end-Cretaceous events (McGhee *et al.*, 2004). Pollen records show that many seed ferns became extinct, as did some other plant groups, but a lack of a detailed floral record for the interval has hampered analysis in Europe. In eastern North

America the boundary is well preserved in the Newark Supergroup and approximately 60% of the pollen species disappeared within approximately 500,000 years. Similar patterns have been found in Arctic Canada but not in Australia or Siberia, possibly indicating considerable regional variation in extinction intensity. Of particular relevance is a sharp increase in the abundance of fern spores at the extinction, reminiscent of the fern spike associated with the K/T extinction. Whether or not any vertebrate extinctions occurred remains highly contentious. One analysis of the Newark group vertebrates indicated extensive extinctions, but this conclusion has been challenged by many vertebrate paleontologists who have argued that the Newark Supergroup record is sparse and there are no other data supporting an extinction of terrestrial vertebrates.

Debates concerning the causes of the Late Triassic extinction event are similar to those of the Late Permian. The hypothesis of an extraterrestrial cause was effectively rejected when accurate dating of the leading candidate crater, the Manicouagan impact crater in Quebec, showed that it formed some 13–14 million years before the extinction event, in the middle of the Norian stage. Other Late Triassic craters and horizons of impact ejecta likewise represent pre-Rhaetian impacts that appear to have caused no measureable rise in extinction rates (Walkden *et al.*, 2002). Most attention is now focused on sea-level changes and the effects of global warming triggered by flood basalt volcanism.

Evidence from fossil soils and from fossil leaves of plants related to modern *Ginkgo* has shown that atmospheric carbon dioxide levels rose from less than 1000 ppm to between 2000 and 5000 ppm across the Triassic/Jurassic boundary, with values returning to pre-extinction values within the Hettangian (Schaller *et al.*, 2011). This rise in carbon dioxide levels is hypothesized to have resulted in global warming, with corresponding effects on marine and terrestrial systems as those recorded for the Late Permian event. The similarity with the Late Permian crisis also extends to the involvement of a major igneous province as a source of the carbon dioxide. Recent age dates reveal that the Central Atlantic Magmatic Province, an extensive region of flood basalts extending across eastern North America, Europe, northwest Africa, and northeastern South America that marks the rifting of Pangaea and the initial opening of the Atlantic, erupted coincident with the Late Triassic mass extinction (Marzoli *et al.*, 1999). The eruptions would have released volcanic gases including carbon dioxide into the atmosphere, with serious consequences for climate, ocean circulation, and the biosphere.

End-Cretaceous

What caused the demise of the dinosaurs 65 Ma? This has been both a popular and a scientific question almost since the fossils of these remarkable beasts were first discovered in the early half of the nineteenth century. When the leading explanation became the impact of an extraterrestrial object, both popular and scientific interest exploded. Along with the dinosaurs, other large vertebrates disappeared as well as a wide variety of marine organisms, but overall extinction magnitudes during the end-Cretaceous event were much lower than those of the

other four major intervals of biotic crisis (McGhee *et al.*, 2004). The end-Cretaceous event is the most recent, most studied and has the best fossil record of the five great mass extinctions.

Among marine organisms, 16% of the families and 47% of the genera disappeared. In common with other extinctions, some groups suffered more than others. Ammonites were wiped out completely, and the final extinction of this iconic group has been intensively studied. Problems of preservation and sampling mean that an instantaneous mass extinction can produce an apparently gradual pattern of disappearance leading up to the extinction horizon (MacLeod *et al.*, 1997). One way to address this problem is to undertake statistical analyses of fossil occurrences. In an analysis of 28 Maastrichtian ammonite species from the coast of northern Spain, Marshall and Ward (1996) demonstrated that 25% probably became extinct gradually during the several million years leading up to the Cretaceous/Paleogene (formally Cretaceous/Tertiary, or K/T) boundary; the disappearance of up to 35% is probably linked to an episode of sea level fall just prior to the boundary; and the remaining species probably went extinct right at the boundary (Figure 4; Marshall and Ward, 1996). Other groups that suffered catastrophic extinction include the planktonic foraminifera, a group of very abundant, floating single-celled organisms that produce calcareous skeletons. In contrast, benthic foraminifera, which live on and in the sea-floor sediment, suffered ecological disruption but little apparent extinction.

Broadly speaking, benthic organisms suffered lower extinction rates than pelagic or planktonic ones. Even amongst the benthos, some groups were evidently more extinction prone. A detailed study of sea urchins by Smith and Jeffrey (1998) has shown that feeding strategy strongly correlates with survival, hinting that the extinctions may have been driven by changes in food supply. In contrast, amongst bivalves, the lineages that tended to survive were those with broader geographic ranges (Jablonski and Raup, 1995). The factors controlling survival during the end-Cretaceous mass extinction thus appear to have varied between groups and were also different to factors that appear to control evolution during normal, background times.

Unlike many invertebrates, the problem with vertebrates is that the scarcity of their bones makes them largely unsatisfactory for documenting the pace of the extinction. North America contains one of the best records of vertebrate diversity, and studies have shown that different groups experienced very different extinction patterns. Sharks, marsupial mammals, lizards, and dinosaurs suffered very high extinction, whereas frogs, salamanders, turtles, placental mammals and crocodiles suffered virtually none. Evidence is emerging that Mesozoic birds also suffered major extinction at this time. Both large and small vertebrates are part of the list of extinct forms, countering earlier claims that only large vertebrates became extinct. Animals in freshwater settings suffered much less extinction than fully terrestrial forms: approximately 90% of freshwater forms survived but only 12% of the land species survived. Most scientists accept that the last dinosaurs disappeared about a meter or so below the extinction horizon in North America, but there is still some uncertainty whether dinosaurs were in decline prior to the impact. A few remains are known from rocks that postdate the extinction, and while

Figure 4 Graph showing the observed temporal ranges and occurrences (short horizontal lines) of 28 species of ammonites at a K/T (K/Pg) boundary section in Spain. Since the observed ranges underestimate true ranges, they can be corrected by statistical analysis. The 50% and 95% confidence intervals on the final occurrences are represented by the small squares and inverted triangles, respectively. Species that extend beyond the boundary are indicated by arrows on their ranges. The species are classified into three categories: (1) those that became extinct prior to the boundary, (2) those that may have become extinct due to either impact or a decrease in sea level shortly before the boundary, and (3) those that became extinct at the boundary. Discussion and further details are provided in [Marshall and Ward \(1996\)](#). Reproduced with permission from Pope KO, d'Hondt SL, and Marshall CR (1999) Meteorite impact and the mass extinction of species at the Cretaceous/Tertiary boundary. *Proceedings of National Academy of Science USA* 95: 11028.

claims for dinosaurs persisting after the end of the Cretaceous have generally been dismissed, the possibility remains that some did survive for a short time in those regions where the terrestrial extinction was much reduced.

Amongst terrestrial plant communities, a remarkable increase in the abundance of fern spores appears at the boundary in sites throughout North America and coincides with the iridium spike and the occurrence of shocked quartz. The interpretation is that these ferns represent the pioneering

community that blanketed the bare ground following the extinction of the other plants. In western North America, an extinction of almost 80% of plant species has been documented. Further afield, however, the crisis is less evident so that in Antarctica and New Zealand the extinction is almost unrecognizable.

In 1980, Luis Alvarez and colleagues published one of the most influential geological papers of the twentieth century, in which they hypothesized that an elevated iridium

concentration in a thin clay layer at the Cretaceous/Palaeogene boundary section at Gubbio, Italy, was the result of the impact of a 10-km wide asteroid and that the impact caused the extinctions. Iridium is extremely rare in crustal rocks on Earth, but much more abundant in meteorites, which are the source of nearly all of the iridium present on the surface of the Earth. Any spike in iridium concentrations in sedimentary rocks suggests either a significant depositional hiatus or an increase in the rate of extraterrestrial material reaching the planet's surface. A spectacular way to enhance the delivery rate of iridium is through the impact of a large asteroid. As predicted by *Alvarez et al. (1980)*, the iridium anomaly has since been discovered at many other K/T boundary sections, both marine and terrestrial, and other indicators of an extraterrestrial impact have also been recovered, including shocked quartz. The discovery of an impact crater of the correct age and approximately 200 km in diameter at Chicxulub in the Yucatan Peninsula, Mexico, was the final convincing piece of evidence that *Alvarez et al. (1980)* were correct and a large impact had indeed occurred. But, did this impact cause the extinctions?

The Chicxulub bolide is believed to have come from the southeast and North America probably felt the greatest effect of the blast, which might account for the higher terrestrial extinction rates there. Many of the supposed extinction-causing consequences of the impact have, however, proved controversial. The suggestion that terrestrial biotas were decimated by continental-scale wildfires is not supported by measurements of the amount of charcoal in rocks (*Belcher et al., 2003*). The theory that dust from the impact would have plunged the world into a lengthy period of photosynthesis-sapping darkness is not supported by detailed modeling (*Pope, 2002*). Whether the amount of water vapor and sulfur dioxide thrown into the atmosphere by the impact would have significantly cooled the Earth for a long period and produced extensive acid rain is open to debate. The second hypothesis of the *Alvarez et al. (1980)* paper, that an extraterrestrial impact caused the end-Cretaceous extinction, is not universally accepted by all scientists.

The latest Cretaceous was a time of considerable environmental change and other causal mechanisms have been proposed. Although the Cretaceous was a greenhouse period, with elevated temperatures and carbon dioxide levels, the final 100,000 years were much cooler overall, with, as already noted, a major episode of global sea level fall happening just prior to the boundary. Some ammonite species, at least, disappeared then. In common with the Late Permian and Late Triassic mass extinctions, the end-Cretaceous event also coincides with the eruption of a large flood basalt province: the Deccan Traps in India. If the eruption of flood basalt provinces led to extinction-causing environmental changes at earlier times in Earth history, it seems unlikely that the Deccan eruptions would have had no effect on the Cretaceous biota. According to one study, ecological disruption of the plankton through the latest Cretaceous and earliest Palaeogene at a number of sites across the globe seems to correspond to intervals of eruptive activity (*Keller, 2005*). While the existence of an impact coincident with the extinction seems indisputable (e.g., *Norris et al., 1999*), the various proposed kill mechanisms are disputed and the alternative hypotheses that climatic or environmental changes were responsible for at least some of the extinctions has yet to be rejected.

Lesser Mass Extinctions

Within the fossil record a number of smaller extinction events have been identified (e.g., *Hallam and Wignall, 1997*; for postextinction recoveries, see *Erwin, 1998*). Many of these events are not well studied, and a few only appear on large-scale, synoptic analyses (compare, e.g., some of the diversity troughs in *Figures 1* and *3*), while others may be statistical artefacts. Several of these events are significant however, and they provide a useful perspective on the larger mass extinctions. They also emphasize the continuum in biotic disturbances between the great Late Permian mass extinction and the less extreme but more common biotic crises, which do not qualify as mass extinctions. With current scientific endeavor seeking to predict future consequences of current climate change and biodiversity loss, these extinction events are highly relevant to the present day as they contain archives of global-scale experiments in global warming.

Neoproterozoic and Paleozoic

What happened to the enigmatic, soft-bodied Ediacaran biota of the late Neoproterozoic? This diverse assemblage of metazoans is found worldwide and includes a diverse assortment of cnidarian-grade organisms and a few probable ancestors to the clear metazoans of the Cambrian. Virtually all the Ediacaran forms disappear from the record prior to the base of the Cambrian. Whether this represents a mass extinction, a change in preservational style so that Ediacaran fossil were no longer preserved, or a gradual replacement of these forms by diversifying animals is unclear.

The Early Cambrian is characterized by a diverse assemblage of small shells, spicules and tubes, trilobites, and the sponge-like archaeocyathids. Two pulses of extinction near the end of the Early Cambrian each eliminated approximately 40–50% of marine genera. Reefs, small shelly fossils, and some brachiopods were particularly affected. These extinctions mark the end of this characteristic fauna and paved the way for the trilobite-dominated marine communities that dominate the remainder of the Cambrian. Metazoan reefs did not reappear again until the Ordovician, when the origination of the Paleozoic corals (tabulates and rugosans), bryozoans, and some sponges heralded a new suite of reef-builders that lasted until the Late Permian. The causes of these events are unclear, but marine anoxia, a decrease in sea level, and possibly changes in atmospheric composition have been suggested. Equally puzzling are a series of crises affecting near-shore trilobites and other marine benthos during the Middle and Late Cambrian in North America. Each event begins with a radiation of new trilobite families across marine shelves, evidently from deeper water ancestors. These new forms are initially widespread, with broad environmental tolerances. The new forms rapidly produce a diverse, endemic trilobite assemblage, in which individual taxa have relatively narrow environmental tolerances, that is then wiped out by a sharp extinction event that cuts across different marine environments. Brachiopods, conodonts, and other marine taxa are also affected. Although the extinctions were initially linked to decreases in sea level, with the diversifications occurring as sea

level increased, other paleontologists have suggested temperature decreases or incursions of low-oxygen waters. At least four of these events occurred from the Middle Cambrian into the earliest Ordovician, with the interval between extinctions being about 4 million years.

Mesozoic

A number of Mesozoic extinction events have been proposed. Two of the most prominent occurred in the earliest Toarcian and at the Cenomanian/Turonian boundary (Hallam and Wignall, 1997). If the Paleobiology Database analyses are correct, then the Jurassic/Cretaceous boundary also may be a significant event in the Mesozoic (Figure 3).

The Cenomanian/Turonian (C/T) mass extinction during the Late Cretaceous (93.5 Ma) eliminated approximately 8% of marine families and 26% of marine genera. Statistical analysis of extinction patterns from western USA suggests the extinction occurred in many discrete steps. Benthic organisms were particularly affected, whereas cephalopods and other groups living high in the water column suffered relatively little extinction. The crisis occurred during warm, equable climates, relatively high sea level, and is associated with marine anoxia and the formation of black shales. In England, for example, the C/T boundary forms a well-known “black band” in quarries. The greenhouse climate evidently led to sluggish oceanic circulation and warm, saline bottom waters, which stratified the oceans and aided in the formation of anoxic conditions (Harries and Little, 1999).

There are some remarkable similarities between the C/T event and an earlier mass extinction during the early Toarcian (Harries and Little, 1999). The extinction intensities were essentially identical, as were the environmental changes recorded, especially in northwestern Europe, which was particularly affected by this event. As with the C/T event, the early Toarcian crisis primarily eliminated benthic taxa, particularly bivalves, gastropods, and brachiopods, as well as many ammonites. In both extinctions diverse faunas were replaced by a much less diverse, stressed fauna dominated by epifaunal bivalves and ammonites. The early Toarcian extinction is clearly associated with global warming and the expansion of oxygen-poor waters in many ocean basins. As with the Late Permian event, however, anoxic waters were not present everywhere; and yet in regions with no record of oxygen stress, such as Spain, the extinction can still be recognized.

Cenozoic

The Cenozoic experienced many smaller biotic crises, each associated with climatic shifts, both cooling and warming. The most recent extinction – that of large mammals during the late Pleistocene – is also associated with human hunting, and whether climate or hunting was the primary cause is the subject of continuing debate.

The late Eocene to early Oligocene was an interval of heightened extinction both on land and in the oceans, although correlation between the two realms remains difficult. Approximately 80% of the foraminifera disappeared, and molluscs and echinoids (sea urchins) display a prolonged period of increased extinction, evidently due to a period of global cooling, which appears to have been the primary factor

in the marine extinctions. The same is true on land, where the latest Eocene or earliest Oligocene marks the disappearance of many primitive mammal groups and the rise of modern mammals. Primates and rodents suffered considerable extinction, as did aquatic crocodiles and turtles (Hallam and Wignall, 1997).

The most recent mass extinction occurred within the past 100,000 years, and some claim it continues today. Many large mammal species disappeared from Europe, North and South America, and Australia; only in Africa were they unaffected. In North America, mammoths, mastodons, camels, saber-tooth cats, ground sloths, and a host of other animals disappeared approximately 10,000–12,000 years ago. A similar pattern is found in northern Europe. The leading explanation for this extinction is the overkill hypothesis, with human hunting the most important factor. Proponents of this view note that humans became important ecological factors in each region about the time that the pace of extinction increased. Opponents have favored climatically driven extinction, although the nature of the climatic change has been continuously modified to accommodate new information. The overkill hypothesis has also been extensively criticized.

Modern Examples of Extinctions

Gábor L Lövei, Aarhus University, Slagelse, Denmark

Glossary

Extinction Disappearance of the last living individual of a species. Extinction can be “local ~”, if it concerns a definite population or location; we speak of “~ in the wild” when the only individuals alive of a species are in captivity; and of “global ~” when no living individual remains of a species.

Extinction cascade A chain of extinctions triggered by the extinction of a particular species on which many others depend. Species affected by other species are directly (parasites that live only on that species) or indirectly (predators that rely heavily on the species for food) linked with the extinct species through ecological links. Most species support other ones: a number of specialist herbivores can depend on a plant species for food, or many parasites are host-specific (can only parasitize one species). When these supporting species die out, the dependent species also go extinct. This can trigger a chain of extinctions, the “~”. For example, when the passenger pigeon died out, at least two feather lice parasites followed it into extinction. “Co-extinction” occurs when more than one species die out at the same time (this by definition must happen when the host of an obligate parasite dies out).

First-contact extinctions A wave of extinction of species native to a continent or island, following the first arrival of humans to that area.

Living dead A term coined by the American tropical biologist Daniel Janzen, denoting the last living individuals of a species destined to extinction. By definition, extinction happens when the last individual of a species dies. In reality, however, extinction of a species can be certain even earlier. Most species need both males and females to

reproduce. If there are no fertile individuals of one sex, the species is doomed to extinction even if several individuals are still alive. Similarly, below a certain population size, a species cannot form a self-sustaining population, and its numbers dwindle. The decline may take many years but its course cannot be easily altered.

Metapopulation A group of populations belonging to the same species that are connected *via* regular migration to each other's habitat patches. An important recent realization is that most species exist as metapopulations and that this is probably the original, ‘natural’ state of all species.

Pseudo-extinction Extinction of local populations is sometimes erroneously termed as ‘pseudo-extinction’. This is misleading because global extinction proceeds through the stepping stones of extinctions of local populations. There is no fundamental distinction between the extinction of a local population and the extinction of a species other than the fact that species becomes extinct when the last local population dies out.

Proximate cause(s) of extinction The actual immediate agent(s) that cause(s) a species to become extinct.

Recolonization The reappearance of a species in an area where it has earlier been present, then became extinct.

Species life span The time between the first appearance of a species in the fossil record and its final disappearance. This time span is typically in the range of millions of years.

Ultimate cause of extinction Being rare (few in numbers) and of limited distribution are precursors to extinction. The causes leading to rarity are the ultimate causes of extinction.

Species Life Spans

The life span of a species can vary widely but no species lives forever. Fossil records indicate that the average life span of an invertebrate species is about 11 million years, while mammal species live for about 1 million years (Table 1). Species existing today form only a small fraction of species that have ever lived. If we assume that the average life span of a species is 5–10 million years, and multicellular organisms have been present on Earth for a period of 600 million years, the plant and animal species currently living are not more than 1–2% of all those that have ever lived. For marine invertebrates, an estimated 95% of the species that had ever existed are extinct (Jablonski, 1994). Extinction is thus the natural fate of all living species.

Extinction can and does happen at any time, and extinctions occur continuously. Most of these extinctions are of local populations. For many species, a landscape contains several suitable habitat patches but not all patches are occupied at all

Table 1 Estimates of species' lifespans, from origination to extinction

Group	Estimated life span, million years
Dinoflagellates	13
All invertebrates	11
Cenozoic bivalves	10
Diatoms	8
Planktonic foraminifera	7
Echinoderms	6
Marine invertebrates	5–10
Marine animals	4–5
Cenozoic mammals	1–2
Mammals	1
All fossil groups	0.5–5

times. Species constantly recolonize unoccupied patches and go extinct in others. The local populations in these patches form a kind of network called a 'metapopulation'. There is constant migration among the habitat patches, some of them (source patches) producing surplus individuals that colonize other patches; others are not so productive (sink patches). When a metapopulation cannot produce enough individuals to compensate for mortality, the species will become regionally extinct. This will result in a range contraction as regular migration between metapopulations does not occur.

Species may become globally rare and subsequently go extinct at any time. The 'background rate of extinction' is estimated at 1–10 species/year through the geological periods (Dirzo and Raven, 2003). However, significant extinctions in Earth's history occurred in clusters. During the last 500 million years, there were five such "mass extinctions", wiping out large proportions of the then-living species. The fossil record related to these has been intensively studied and hotly debated, but without producing an accepted interpretation about their causes. Extinctions, affecting a more restricted group of species have also occurred on a smaller scale. Within those groups the extinctions were significant.

The most recent of such events commenced during the late Quaternary, about 100,000 years before present (yBP), and started to intensify about 40,000 yBP. Since then, several hundreds of land vertebrates, mostly large species (>50 kg body mass) have gone extinct on different continents and islands, at different times. This extinction wave has not yet ended.

Examples, Postglacial

North American Extinctions

In late glacial North America (called the Wisconsin glaciation period, ending about 10,000 yBP), 71% of mid-latitude mammal genera were lost, while in Alaska, the same loss was 56%. This is the opposite that would be expected from environmental conditions – we expect that if climate is the cause of these extinctions, more northerly species would be more severely affected. According to their trophic position, 71% of the herbivores, 67% of the bears, and 50% of the dogs and cats became extinct. Many of these have lived through cycles of glacial and interglacial periods, and extinction was not biased toward either older or newer genera. Environmental changes are unlikely to have caused these extinctions. On the contrary – general conditions were at their worst during the period preceding the extinctions – 20,000–18,000 yBP. Conditions for large mammals have improved afterwards, notably so between 18,000–7000 yBP, when most extinctions occurred.

The postglacial extinctions are generally connected to the appearance of humans in the regions affected. The North American continent has suffered numerous avian extinctions during the end of the last glacial when 19 bird genera became extinct. In spite of taxonomic problems as well as scarce records (10 of these birds are only known from the single area of the Rancho La Brea tar pits in metropolitan Los Angeles, USA), we can generalize that most of these extinct birds were large to very large by avian standards, and the loss of most or all of

them can be attributed to ecological dependency on large mammals that also went extinct during the same time. The largest group of these extinct birds were raptors: condors, eagles, accipitrid vultures, and caracaras. Extant hunting birds, including eagles, feed on carrion as well as live prey that they themselves captured; probably the same was true for these birds. The disappearance of large mammals must have resulted in a significant reduction of the available food base, and many of them became extinct. A similar extinction cascade can be observed in the only remaining continent with diverse large ungulate fauna, Africa: where game becomes scarce or disappears, vultures and eagles also disappear. This points to the ecological plausibility of this hypothesis. Two other birds, *Panandris* and *Pyelorchamphus*, related to the North American icterids (Icteridae) of today, are thought to have been in a commensalist association with large herbivores – the 'cowbirds' of the Pleistocene – and followed their hosts into extinction. In Africa, there are several groups of songbirds associated with large mammals, such as oxpeckers and drongos. It is likely that a variety of commensalist relationships also existed in the New World, and these must have been lost with the disappearance of most large mammals in North America.

Australian Extinctions

Australia, until the end of the last glacial, had a fauna of monotremes and marsupials that was as diverse as the placental faunas of other continents. In contrast to those, however, the Australian fauna was rich at the species if not the genus level, and it was not subjected to any significant intercontinental faunal exchange. This led to a homogeneous fauna that seems to have been unable to withstand ecological stress. During the late Pleistocene, many species went extinct. This loss was comparable, in numbers of species, to extinctions on other continents. For example, while there existed only 15 genera versus the 32 in North America, the number of extinct species is about 60 in Australia and 51 in North America. All 19 species of marsupials heavier than 100 kg, and 22 of the 38 species that are 10–100 kg, have become extinct. Three reptiles and the ostrich-sized *Genyornis newtoni* have met the same fate. A few of the extinct animals are depicted in **Figure 1**. The largest reptile was the varanid lizard *Megalania prisca*, which, at 7 m length, was probably a top predator. Among the extinct monotremes were large echnidas, such as *Zaglossus hacketti*, which was 1 m long and 0.5 m tall. This seems to have been a proportionately large version of the small living echnida. Among the marsupials, there were large carnivores: a large morph of the tiger cat (present on one island until European contact), or the leopard-sized *Thylacoleo carnifex*, a marsupial lion named 'giant killer possum'. One species of the koalas, *Phascolarctos sirtoni*, that was about 30% larger than the living koala, also survived until the very late Pleistocene. The living koala is the only survivor of a diverse family that had its peak in the Tertiary.

The large and varied superfamily of Diprodontoidea has totally disappeared during the late Pleistocene, completing a longer sequence of decline. By the last glacial, only two families were represented. Some species of the Palorchestidae

Figure 1 A bestiary of most extinct late Pleistocene Australian vertebrate species. The silhouettes are drawn to scale, with the scale indicated by the human shape. The species, from left to right, are: Row 1: *Palorchestes azcal*, *Zygomaturus trilobus*, *Diprotodon optatum*, *D. minor*, *Euowenia grata*. Row 2: *Thylacoleo carnifex*, *Ramsayia curvirostris*, *Phascolonus gigas*, *Phascolomys major*, *P. medius*, *Vombatus hacketti*, *Phascolarctos stirtoni*, *Propleopus oscillans*. Row 3: *Proctoptodon goliah*, *P. rapha*, *P. pusio*, *Sthanturus maddocki*, *S. browni*, *S. occidentalis*, *S. orientalis*. Row 4: *S. gilli*, *S. atlas*, *S. tindalei*, *S. pales*, *S. oreas*, *S. andersoni*, *Troposodon minor*, *Wallabia indra*. Row 5: *Protemnodon roechus*, *Panak*, *P. brehus*, *Macropus ferragus*, *M. birdselli*, *M.siva*, *M. titan*. Row 6: *M. rama*, *M. thor*, *M. piltonensis*, *M. gouldi*, *M. stirtoni*, *Sarcophilus naliarius*, *Zaglossus hacketti*, *Z. ramsayi*. Row 7: *Progura naracoortensis*, *P. gallinacea*, *Genyornis newtoni*, *Megalania prisca*, *Wonambi naracoortensis*. Reproduced with permission from Murray P (1984) *Extinctions down under: A bestiary of extinct Australian late Pleistocene monotremes and marsupials*. In: Martin PS and Klein RG (Eds) *Quaternary Extinctions: A Prehistoric Revolution*, pp. 600–628, with permission from University of Arizona Press, Tucson.

were beasts that resembled a giant kangaroo but had a tapir-like trunk and huge, curved claws. The cow-like *Zygomaturus trilobus* had a 2 m long body, a huge, broad head, and a narrow, upturned snout. Judging from the frequent fossil remains, it was widely distributed in coastal and mountain Australia. Another browser was the large, slow *Diprotodon optatum* that had a feeding apparatus suggesting that it was browsing tough, succulents and shrubs. The kangaroos (family Macropodidae) today are the largest group of marsupials still living in Australia, although their diversity, too, was seriously reduced by the beginning of the Holocene. From the *Macropus* genus itself, at least eight species died out. Some of these were small, like today's wallabies, but *Macropus titan* and *M. ferragus* were real giants, the latter reaching a height of more than 2.5 m and a body mass of 250 kg. If these species have a living relative, these are about 25% or more smaller.

Although Australia has been inhabited by humans since at least 50,000 yBP, the extinctions were generally not believed to be linked to their presence. Recent evidence based on more exact radiocarbon dating of bid and egg remains casts doubt on this belief, and human predation seems the probable cause also in Australian extinctions.

African Extinctions

When examples of modern extinctions are discussed, Africa is often ignored. Some have called Africa 'the living Pleistocene' because this is the only continent where a diverse and abundant fauna, that bears any resemblance to the Ice Age, remained. However, Africa has had its postglacial extinctions

and as this is the continent with the longest period of human occupation, the analysis of these is potentially very important.

The most impressive examples of such extinctions come from northern Africa. This region, after the dry, hyperarid period between 40,000–12,000 yBP, experienced a moist period during which the fauna included, among other species, the African elephant, white rhinoceros, a zebra, warthog, giraffe, blue wildebeest, hartebeest, eland, roan antelope, and a species of reedbuck. Between 5000–4000 yBP, this moist period changed again, and this fauna disappeared from most of the Sahara, but survived in the Maghreb area of North Africa. Some species were certainly lost, though: the Atlantic gazelle (*Gazella atlantica*), Thomas' camel (*Camelus thomasi*), the giant North African deer (*Megalocerus algericus*), and the long-horned North African buffalo (*Pelorovis antiquus*).

A similar cycle can be observed in southern Africa, although well-dated records are missing from most of this region. In the Cape zone, however, the total disappearance of the long-horned buffalo, giant hartebeest (*Megalotragus priscus*), the giant Cape horse (*Equus capensis*), and the southern springbok (*Antidorcas australis*) happened around 12,000–9500 yBP. Their extinction in southern Africa was, at least partially, related to climate-driven environmental change.

During this period, however, there was a dramatic change in artefact traditions throughout the continent, indicating a very significant shift in human cultures, and with this, probably of hunting techniques and efficiency. Analyses of archeological sites support the hypothesis of increased hunting proficiency: more remains of individuals in their prime age were found as well as relatively more bones of 'dangerous game'. In North Africa, the appearance of domesticated animals may also have contributed to the decline.

The pace and extent of late Pleistocene and Holocene extinctions in Africa parallel that of Eurasia, where there was no sudden and massive extinction wave such as in North America. The only significant difference between these continents and the Americas is the length of human occupation. After Africa, Eurasia has the longest period of human presence, about 700,000 y. North America did not have a previous history of human habitation, and the pattern of extinctions is entirely different. This continent was swept by waves of extinction during the late Pleistocene/early Holocene, coinciding with the migration through the Bering Strait and then southwards of anatomically modern humans. During this period, a very large proportion of the extant fauna disappeared in what is geologically and evolutionarily very short period of time.

Examples, First-Contact Extinctions

On small islands all over the world, many species, especially birds, went extinct during the last 10,000 years (islands have an impoverished mammal fauna to start with, due to dispersal problems). The other common feature of these extinctions is that there was no taxonomic replacement of lost species. These extinctions are so tightly correlated with the arrival of humans, that they were termed 'first-contact extinctions' (FCEs). In the Americas, FCEs occurred between 12,000–10,500 yBP, on the West Indies 7000–5500 yBP, and on Madagascar, 2000–500 yBP (MacPhee and Marx, 1997).

These FCEs can take as little as 1 year on small islands, and up to 1500 y on large islands and continents. On the Commander Islands, east of the Kamchatka Peninsula in the northern Pacific Ocean, humans arrived in 1741. Steller's sea cow (*Hydrodamalis gigas*) was extinct by 1768. On the Mascarene Islands, humans arrived AD1600, and the major extinctions terminated around 1900. In New Zealand, the first human colonists arrived at around AD 1000, and the first major episode of extinctions terminated by AD 1500. In the Mediterranean, humans colonized all the major islands between 10,000–4000 yBP – this also coincides with the extinctions of several endemic species, such as pigmy elephants, rhinoceroses, and hippopotamuses.

Madagascar

The extinction of large mammals and birds on the island of Madagascar during the Holocene was of similar magnitude than the earlier, Quaternary extinctions in North America, Australia, and New Zealand. Today's Madagascar fauna is a pale shadow of a once-diverse assemblage of spectacular species. Humans colonized Madagascar only in historical times. The earliest dated archeological site is from about AD 500. The extinctions started to happen not much later. It is generally agreed that these extinctions were caused by human activities; opinion only differs in what type of activity this was.

Seven of the 17 primate genera have disappeared completely, and two more lost its largest species. The extinct lemuroids were all large, and probably diurnal. The largest of these, *Megadalapis edwardsi*, had males with a body mass between 50 and 100 kg. Members of the smallest extinct genus (*Mesopropithecus*) were about as large as the largest living species, the indri (*Indri indri*). Several of these species had ways of locomotion that are unknown among today's living primates: walking on the ground on four legs (*Hadropithecus*), arm-swinging (*Paleopropithecus*), and vertical climbing similar to that of the koala bear (*Megadalapis*).

The other group that was severely affected includes the large, flightless birds, ratites, commonly known as elephant birds. They are classified into two genera and six to 12 species. The largest of them (*Aepyornis maximus*) had a height of nearly 3 m, and resembled a massive ostrich. The smallest, *Mullerornis betsilei*, was about half this size. These species are thought to have been terrestrial grazers – this ecological group is otherwise only represented by the pigmy hippo (*Hippopotamus lemerlei*). This species, together with a large viverrid (*Cryptoprocta spelea*), and an endemic aadrvark (*Plesiorycterops mada-gascariensis*) is also extinct. *C. spelea* was the largest known carnivore in Madagascar, and resembled a short-legged puma – so much that earlier it was classified into the cat family (Felidae). The only reptiles that went extinct were giant land tortoises. The two species had carapace lengths of 80 cm and 120 cm, respectively, and were important consumers of ground vegetation.

The Pacific Islands

Humans have gradually colonized the world, and have arrived at several oceanic islands relatively recently. The colonization

history of the Pacific islands is relatively well studied. The human expansion across the Pacific, starting from SE Asia, was accompanied by a wave of bird extinctions on all the islands that humans reached. The time span of this varied due to facts such as distance from neighboring islands, area, and terrain – but the scale of the human-driven extinctions is huge. On all the Hawaiian Islands, we know more endemic species from fossil records only than the number of such species now extant, i.e., more than half the endemic species were lost after human arrival. Every island in Oceania had lost, on average, an estimated 10 species. The total number of islands is about 800, so the loss of species or populations totals 8000. Rails have especially suffered. All Oceanic islands studied so far have had one to four endemic species of rails, and thus an estimated total of about 2000 species, equaling 25% of the global species richness, was lost during human colonization of the Pacific. Most of these species were flightless forest dwellers.

New Zealand

The New Zealand archipelago lies in the southern Pacific Ocean, between the latitudes of 30° and 47°. It is composed of two large and about 300 smaller islands. This land was originally part of the ancient supercontinent of Gondwanaland that also included Antarctica and the other southern hemisphere continents. New Zealand separated from Australia about 75 million yBP and while there are doubts about the Gondwana origin of its species (there being no proof that dry land has been continuous since the separation), the flora and fauna of New Zealand demonstrate a high degree of endemism. Before the arrival of man, the only mammals were marine species and two small bats. There were no large predatory vertebrates, and in their absence, birds prospered. Many species arriving there with the power of flight had become unable to fly, but the best known birds, the ratites, were originally flightless. The New Zealand ratites belong to two orders: the Apterygiformes (kiwis) and the Dinornithidiformes (moas). They have probably been separated from their relatives since the Cretaceous. The kiwis remained small, unobtrusive and nocturnal, and survived into the present.

Moas diversified into several species; current opinion accepts the existence of nine of them. All were ostrich-like, flightless, herbivorous birds with a considerable size range. The largest moa, *Dinornis giganteus*, was about 2 m tall and weighed up to 250 kg, while the smallest, *Megalapteryx didinus*, was about the size of a large turkey, with an estimated mass of 25 kg. In contrast to earlier opinion, most species were probably inhabiting forests, not grasslands. No species of the moas are left and this is one of the best known examples of large-scale human-caused extinctions.

Polynesians have successfully colonized New Zealand about 1000–800 yBP and although we have no reliable record of moa densities before or after this period, nor do we know much about moa evolutionary history in earlier ages, it is well documented that the cause of their demise was that Maori have intensively hunted all species. Archeological sites with large amount of moa bones are found all over New Zealand, some covering many hectares. The most detailed research on them was conducted on the eastern side of the South Island,

and these convincingly demonstrate that man was a voracious hunter of moas: their nests were robbed, and their carcasses were probably utilized in a wasteful way. Dogs and rats introduced by man have probably also played a role in the extermination of moas, especially the smaller species. Moa hunting became intensive about one century after the arrival of the Maori, coinciding with a rapid growth in their numbers. Within a few centuries, hunting and forest burning accelerated the decline; by about 400 yBP, moas became so scarce that they were no longer systematically hunted. Continued habitat destruction, sporadic hunting and probably predation by feral dogs continued to destroy birds, and none were left by the time of European settlement.

The extinct bird species that have never been seen by Europeans include not only the moas, but about 20 other bird species (Tennyson, 2010). These were often flightless (79% of all extinct species), ground-nesting (89%), diurnal (96%), and larger than the closest surviving relative (71%). Fifteen of these were endemic to New Zealand, and five were very similar to living Australian relatives. No less than four of the 15 were rails, thus echoing the extinction patterns of the Pacific islands (see earlier). Other birds lost include a flightless goose (*Cnemiornis calcitrans*), a giant rail (*Aptornis otidiformis*), a swan (*Cygnus sumnerensis*) and several flying birds. A co-extinction with the moas was the disappearance of the giant Haast's eagle (*Harpagornis moorei*), the largest known flying bird; it was probably preying on moa. After the extinction of its prey, or possibly even earlier, when the prey became rare, the predator died out.

Examples, Historical Extinctions (1600–)

Since AD1500, during the 'modern era', extinctions were closely correlated with the European expansion, starting with the discovery of America in 1492. The time span of resulting extinctions differ by species and the area affected, but it gradually expanded to include all areas and habitats of the Earth.

New Zealand

During the European period of occupation in New Zealand (although 'discovered' by the Dutch seafarer Abel Tasman in 1642, settlement by Europeans did not start until about 1840), at least five further bird species have become extinct. There is no doubt that the environmental changes brought by Europeans in about 200 years exceed those caused by the Polynesian occupants during the preceding centuries. This difference, however, is not due to intent but due to the difference in technology. The impact of the initial colonization in terms of extinctions is larger and more obvious because the Polynesians arrived to predator-free islands.

One of the recently exterminated species is the Stephen Island wren (*Xenicus lyallii*), the only known flightless songbird. Stephen Island is a small island in the Cook Strait, between the North and the South Islands of New Zealand. The first specimen of this bird was brought to the lightkeeper's house by his cat. Described as a new species to science, it was

exterminated by the same cat within one year (1894). No person has ever seen a live specimen.

The catastrophic impact of predator invasion is exemplified by another New Zealand story, the rat invasion of Big South Cape Island. Big South Cape Island lies south of the South Island, and harbored several endangered species until 1964, when ship rats (*Rattus rattus*) got on shore from a shipwreck. In two years' time, the rats reached very high densities, and four species of birds endemic to New Zealand, one native bat species (greater short-tailed bat, *Mysticina tuberculata robusta*) and numerous invertebrates became extinct. Other species were removed from the island, and thus, for example, the South Island saddleback (*Philesturnus carunculatus*), a thrush-sized bird, survived.

Many more species of birds, reptiles, amphibians, sea mammals, and invertebrates have also suffered a reduction of their former range. Typically, they became extinct on the main islands of New Zealand, surviving only on offshore ones that were typically – but accidentally – free of introduced mammals. For example, the tuatara, *Sphenodon punctatus* (with its sister species *S. guentheri*), the only living relative of the dinosaurs, has been found in early archeological sites on the main islands. Today it only survives on a few offshore islands. It did not survive on any island where Polynesian rats (*Rattus exulans*) are present, but reaches high densities on rat-free islands. Another example of on-islands-only species is the little spotted kiwi (*Apteryx oweni*) that had only one self-sustaining population on Kapiti Island near Wellington, and the recently discovered Middle Island tusked weta (*Motuweta isolata*, a relative of grasshoppers).

Hawaiian Islands

The Hawaiian Islands are a group of volcanic islands, distant from any other land mass, in the middle of the Pacific Ocean. They were reached by Polynesian settlers at around AD 500. These islands have had a very diverse and unique fauna and flora, and especially the vertebrates were seriously decimated. The best documented, again, are the bird extinctions. The extinct species include two species of flightless geese, flightless ibises, rails, a long-legged owl, a sea eagle, a number of honeycreepers, and at least one species of crow (since 2002, a second species, the Hawaiian Crow, *Corvus hawaiiensis* is also extinct in the wild). Further, there is a group of species that have living populations on one island or another, but not on the one where they were found as subfossils.

The patterns of extinction are strikingly similar to those of New Zealand, except that there are not many songbird extinctions reported from New Zealand. Man-induced changes in Hawaii may have been more extreme, or New Zealand originally did not have many songbirds.

Significant paleo-zoological findings are accumulating and it is difficult to draw a reliable and comprehensive picture about the original fauna of the Hawaiian Islands as well as a proper assessment of the extent and nature of extinctions. However, what we know now indicates that the effect of man as exterminator, direct or indirect, of the fauna of this island archipelago is much more significant than earlier thought. Authorities claim that our previous knowledge of the prehuman Hawaiian

fauna was so poor and extant species richness is so pale with respect to the original one that ecological and biogeographical studies using recently collected data are critically weakened.

The prehistorically extinct birds of the Hawaiian Islands include one species of petrel, at least 10 mostly flightless species of geese, three flightless ibises, eight of rails, three of long-legged owls, one *Accipiter*, two large crows, one large melliphagid, and 15 species of Hawaiian honeycreepers (relatives of finches).

In the early 1980s, 82 endemic bird species were known from the Hawaiian Islands. Fifty-three of these became extinct prehistorically (before 1778, when a British expedition, lead by James Cook, discovered the islands). Area and elevation show significant positive correlations with the number of fossil and historically recorded bird species: small or low islands lost more species than large or high ones. On Molokai, the smallest of the five largest islands, with 676 km² of area and 1515 m a.s.l., there are 21 fossil and nine historically known species. On Hawaii, the largest and highest (10,646 km², 4206 m a.s.l.), three fossil and 23 historic species are known – although more fossil species are expected after more excavations are done.

Extinction Paradoxes

Interestingly, current extinction rates seem to be lowest in areas with a long history of human habitation.

Plant extinction rates in areas with Mediterranean climate are low, ranging from 1% of all species in W Australia to 0.15% in the Mediterranean itself. Current threats to plants are one order of magnitude larger: 10.2–15.2% of species are considered threatened. The suspected cause of the current low extinction rate is a “recording error”: many of the extinctions occurred in the ‘prebotanical age’. Indeed, the current extinction rates are lowest where agricultural cultivation has been the longest, 8000–6000 yBP. This is consistent with the view that most vulnerable species will have been lost by the time botanical investigations started.

Similarly, the proportion of bird fauna extinct on the Pacific islands is inversely proportional to the length of human habitation of these islands: 80% of Hawaii's bird fauna is recently extinct or endangered against 10% on Vanuatu. Hawaii has been inhabited for about 1500 years, and Vanuatu for 4000 years. Pimm and co-workers (1995) argue that the sensitive species have been eliminated by the first colonists before record-keeping began, and thus we have no direct evidence of first-contact extinctions in the Pacific.

Examples, Extinction Cascades

A species' “ecological environment” almost always includes other organisms that are essential for its survival. Species are linked through trophic links – they eat each other. Other vital ecological links include pollination, dispersal of seeds, and providing habitat. For example, bees, birds and bats pollinate flowers, birds and mammals disperse seeds, trees provide nesting holes for birds. The extinction of a species can have reverberating consequences, affecting other species that are,

directly (such as obligate parasites) or indirectly (such as shared predators) linked with the extinct species through such ecological links. Most species support other ones: a plant species can have a number of specialist herbivores that depend on it for food, or many parasites are host-specific (can only parasitize one species). When these supporting species die out, the dependent species also go extinct. This can trigger a chain of extinctions, termed an 'extinction cascade'.

When the last passenger pigeon, a female named Martha, died in the zoo in Cincinnati, USA, in 1914, at least two species of feather lice that were obligate parasites of this species, must also have perished, although there is no mention of this in any list of extinct species.

All moas, a group of nine species of ratites of different size went extinct not long after Polynesians settled in New Zealand. The largest known raptor, the giant Haast's eagle also followed them into extinction. As there are large middens with thousands of moa bones at several sites in New Zealand but these do not contain bones of the eagle, it is thought that the eagle was not a victim of persecution or hunting, but became extinct after its food base, the formerly very common moa, disappeared.

Likewise, several bird species that went extinct in North America at the end of the last ice age are suspected to have died out in an extinction cascade (see earlier).

Problems in our Understanding of Extinctions

We are aware that our knowledge of the actual extent of even recent extinctions is very fragmented and incomplete. There is,

in other words, a huge difference between documented and real extinctions. This is due to a series of reasons. Some of these can be overcome with the development of science, but several of them result from the organisms' biology.

How Many Species are There?

We do not know, even to an order of magnitude, how many species we share the Earth with. Current estimates of global species richness tend to converge to a range from 3 to 15 million species. This has an obvious consequence for the estimation of extinction rates: 1000 species is a different relative share of a global total of 3 million versus 15 million.

Record-keeping is Insufficient/Inadequate

The documentation of extinction is also uneven, both geographically (mostly from islands and the northern temperate region) and taxonomically (higher organisms are better reported).

Since 1500, only 753 animal and 588 plant species are listed as extinct (Table 2). We strongly suspect that even among vertebrate groups, documented extinctions are serious underestimates. For example, on the Solomon Islands, where 164 bird species have been recorded, 12 have not been seen this century, but only one is listed as extinct. In Malaysia, a 4-year search for 266 freshwater fish species reported in the last century found only 122, yet few are recorded as extinct.

Table 2 Species in major taxa that have become extinct since 1600 or are threatened with extinction

	Total number of species			% Extinct	% Threatened in 2008
	Described (thousands)	Extinct since 1500	Listed as threatened in 2008		
Animals, total	1400	753	8465	0.05	0.60
Invertebrates, total	1, 232.40	256	2499	0.02	0.20
Molluscs	81	191	978	0.24	1.21
Crustaceans	40	4	606	0.01	1.52

Total, animals + plants	1642.2	1341	17838	0.08	1.09

Combined from May, *et al.* (1995) and IUCN (2010).

The current method of documenting extinct species is not entirely valid biologically. A species becomes 'officially extinct' with the death of the last living individual. A species may be destined to extinction long before this happens. If mortality surpasses reproductive success, a species may get onto an 'extinction trajectory' – numbers will continuously decrease without reversal, but it will take many years or decades until all individuals perish. Likewise, if there are no reproductively successful pairs remaining, the species has no hope of surviving, even though not all individuals are dead yet. These species are termed the 'living dead'.

Sometimes species can go through a 'genetic bottleneck' when populations become so small that genetic variability practically disappears. One such example is the cheetah (*Acinonyx jubatus*), a fast-running predator in the cat family, which must have gone through such a population crisis some thousand years ago. Today all living cheetahs are genetically virtually identical. The black robin (*Petroica traversi*), a small, endemic songbird on the Chatham Islands of New Zealand, had only one fertile female in the 1980s. In one of the success stories of conservation, this species was brought back from the brink of extinction – but genetic variability of the species is much reduced (although apparently without detrimental effects). Without human intervention, this species would have become extinct.

We also have to consider that so many species are recorded from only one location (for example, up to 40% of beetle species kept in the Natural History Museum collection, London, United Kingdom) that it is difficult to assess anything but local extinctions.

Uneven Recording Effort

Documented insect extinctions are 100 times lower than vertebrate extinctions. The difference is even larger if we consider that there certainly are many more insect species than we know today. Part of this is due to a large difference in the effort we devote to the study these groups. There are 100 times more vertebrate than invertebrate taxonomists, and 10 times more than the number of taxonomists of flowering plants. This uneven attention by humankind to different groups is also evident from the rate of describing new species. This is only 0.03–0.05% new species/year for birds. In tropical areas, one of every 100 plant specimens (1%) is new for science; for insects, fungi, and marine macrofauna, this can reach 20–80%.

Taxonomic and Habitat Bias

Our knowledge is also very biased by habitats and taxonomic relationships. We know much more about forests than seas, and while most of the mammal or bird species of the world are known, this cannot be said of other important and species-rich groups of organisms like fungi, nematodes, or arthropods.

The great taxonomic bias in our records is well exemplified in the 61 extinct insect species: 33 of these are butterflies and moths. These groups do not constitute more than half of all insect species (they are more likely to be about 25%); their

prevalence merely reflects that butterflies are much better studied than other insect groups. It is perhaps realistic that 51 of these are island species but 42 of them are from Hawaii which is certainly overrepresented. Similarly, of the 10 extinct continental species, nine are from North America. This indicates the distribution of researchers, not the real distribution of threatened or extinct species.

Geographical Bias

Our knowledge is particularly scant in areas of the Earth with the highest biological diversity, the tropics. Any change is much better documented in the northern temperate regions where only a minority of the global biodiversity can be found.

The geographical bias and variability reported in the literature include patterns that are real, while others imaginary. Sixty-one percent of all recorded animal extinctions are from islands – this is probably a real pattern. The numerical preponderance of the Pacific Islands is due to both their large numbers and recent human colonization. However, that 2/3 of recent animal extinctions are from North America and the Caribbean, and 20% is from Australia is certainly an artefact. All 45 plant extinctions in Africa include species from the Cape flora, and 2/3 of continental plant extinctions are from North America and Australia. The rarity of such records from South America, Asia and other regions of Africa is surely an artefact.

Methodological Obstacles

Some of the above artefacts are historical and irreparable. Further inaccuracies result because much of extinction information is gathered by paleozoology. We have never witnessed these extinctions, and only remains of the extinct organisms are found. There are special difficulties in studying and interpreting fossil or subfossil material. Just to mention one, the screens used for sieving soil when excavating animal bones have been, until recently, too coarse to retain bones of small bird species. As a natural consequence, our knowledge of the true extent of bird extinctions is grossly biased because there are many more small than large species of birds (just as in other groups of organisms).

Inherent, Biological Problems

Most of our fossils are from marine organisms, mostly because they often have calcareous body parts that fossilize well. Fossilization on dry land is different: some groups in some climatic regions (for example, insects in tropical climates) simply do not fossilize.

Birds are better known than other organisms because their skeletons fossilize better and their taxonomy, generally, is better known. In contrast, the original vegetation of the Hawaiian Island lowlands is a matter of conjecture as it was largely destroyed before botanists arrived to collect there. Entomologists can only speculate what the effect of this deforestation could have been for the arthropods as very few insects are preserved under Pacific island conditions.

Theoretical Aspects of Extinction

The first step in the extinction process for a species is to become rare. It is conceptually useful to distinguish between ultimate causes of extinction (what causes species to be rare and thus vulnerable to extinction in the first case) and proximate causes of extinction (what is the actual cause of extinction). These latter generally include demographic and environmental stochasticity (random, large fluctuations in density and environmental conditions), genetic deterioration and social dysfunction, although their respective importance is not well understood. Ultimate causes include hunting, habitat destruction, invasion by introduced species, and pollution.

There are two general tendencies that are relevant for the study of extinctions.

1. Species that are widespread tend to be abundant as well, but the causes of this positive correlation are not well understood. This also means that species most at risk from extinction (those that are sensitive to proximate causes) have small geographic ranges, because they will also be locally rare. This double jeopardy may be serious when populations and ranges are artificially reduced by ultimate causes of extinction.
2. The distribution of tropical species is generally more restricted than that of temperate species. Smaller ranges have been documented for tropical than temperate-region trees, molluscs, crustacea (crabs and relatives), fish, amphibians, reptiles, and mammals. A related trend is that average population densities of individual species increase from the Equator toward the poles (proven for invertebrates, mammals, and birds). This fits with trend 1 above, and is also consistent with a decline in range sizes toward the tropics.

As a consequence, disproportionately more tropical than temperate species are threatened with extinction. Of the 1029 threatened bird species, 442 live in tropical forests, more than twice the number of species living in wetlands, the next most threatened habitat category.

Most (direct as well as circumstantial) evidence indicates that most of the recent extinctions were caused by humans. Climate change has been invoked in some cases but the evidence for this is not strong. The actual human impact can be overhunting, habitat destruction, voluntary or accidental introduction of non-native species (mostly predators: cats, dogs, rats or browsing herbivores: pigs, goats, sheep). It was also suggested that humans have spread an extremely virulent pathogen, causing a 'hyperdisease'. In molluscs, birds, and mammals, that went extinct since 1600 and have a known cause, 23% were due to hunting, 36% to habitat destruction, and 39% due to the introduction of exotic organisms. Once again, our knowledge is rather sketchy: in mammals that became extinct since 1600, only 30% have an established proximate cause of extinction.

Introductions as a Threat to Species

Introduced species have often been implicated in the extinction of native species. Many introduced species, however, have

had no detectable effect on species in their new environments. The massive spread of organisms by humans to other areas of the globe may increase local diversity, but will result in large losses in global biodiversity. To understand the danger that pan-mixing of the Earth's fauna and flora signify, let us consider a thought experiment in island biogeography. Species richness on an island is largely determined by its area: the larger the area, the more species the island contains. The same applies for continents. For example, mammal species richness is related to the size of the individual continents. The resulting correlation allows us to extrapolate the global species richness. A supercontinent, with an area equal to the total dry land on Earth would support about 2000 mammal species. Currently, there are about 4200 mammal species. Therefore geographical isolation allowed evolution to generate nearly twice the biodiversity that could otherwise, on the basis of habitat area alone, be expected. As today human-assisted invasion is becoming a more and more prevalent biogeographic phenomenon, the individual continents are more and more like one supercontinent. It is not surprising that more extinctions are predicted, with possibly catastrophic consequences for biodiversity.

Often there is more than one cause of extinctions. For example, the kokako (*Callaeas cinerea*), an endemic wattlebird in New Zealand became extinct in most of its former distribution range (and is on the brink of global extinction) due to a combination of factors. These include the contraction and fragmentation of its original forest habitat plus the effects of introduced predators, mainly the European stoat (*Mustela erminea*) and the Australian brushtail possum (*Trichosurus vulpecula*).

Insights from Population Dynamics

A further difficulty in understanding extinction is that the actual process of extinction is also very imperfectly documented. Only a few documented examples exist that link population decline to changes in species distributions. The stepping stones of global extinction are local extinctions, so it is logical to assume that as a species becomes more restricted and rare, its distribution range will become fragmented and gradually smaller. The decline of the European fir tree (*Abies* sp.) was indeed accompanied by population range fragmentation. The skipper butterfly (*Hesperia comma*) in Britain has crashed during the twentieth century. This process left scattered and highly fragmented populations by the 1950s. The same happened with many bird species in New Zealand (kokako, kaka *Nestor meridionalis*, a large parrot or the weka *Gallirallus australis*, a flightless rail).

The sensitivity of fragmented populations is underlined by a trend seen in the success of reintroduction attempts: 76% of 133 documented reintroductions into former "core" areas succeeded while only 48% of 54 translocations to periphery or beyond did so. However, not all species show similar range dynamics in the process of becoming rare. The Kirtland's warbler (*Dendroica kirtlandii*), a small insectivorous bird living in North American forests, withdrew into the historical center of its range during a recent 60% population collapse.

Special Traits Related to Density

While population densities typically fluctuate widely, some species are naturally rare. The study of rarity holds promise to understand processes related to extinction, although only vague clues are available today. It would be important to know, for example, if naturally and anthropogenically rare species are equally sensitive to proximate causes of extinction.

In plants, locally rare and geographically restricted species have lower levels of self-incompatibility, and poorer dispersal abilities. Rare plants are overrepresented in certain families (Scrophulariaceae, Lamiaceae) and under-represented in others (Rosaceae), at least in North America. This may indicate that there are some biological traits and adaptations that are shared by rare species.

Populations of large-bodied species fluctuate less than smaller-bodied taxa (although the measurement of population variability is not as easy as the concept suggests), yet body size is not a useful predictor of extinction risk. In birds, body size was not a useful predictor of rates of population increase or decrease in a global sample of threatened species from 12 families at various trophic levels.

One important but counter-intuitive fact is that trophic position has no consistent effect on extinction. It is difficult to detect a consistent tendency for more frequent extinction of species at higher trophic levels, fossil or extant. This is complicated by the difficulty in separating body size and trophic position (species at higher trophic levels are mostly large). Top predators, in other words, are not more prone to extinction than consumers at other levels.

It seems that large-bodied species are vulnerable to ultimate causes of extinction (hunting, habitat destruction) but less so to proximate causes (their populations fluctuate less).

Time Factor

The above important determinants are thought to vary in ecological time, 10–1000 years. However, as no species lives forever, there may be processes that are operating in evolutionary time. If range and abundance are also species-specific characteristics, some species will be more extinction-prone (i.e., naturally rare and restricted in distribution) than others.

Among songbirds on West Indian islands, older taxa occur on fewer islands, have more restricted habitat distributions and have reduced population densities. However, body size – abundance plots within tribes of birds have more positive relationships than expected in taxonomically ancient tribes, meaning that large-bodied species in old tribes are more common than small-bodied ones. This could be the product of differential extinctions of large-bodied rare species over time.

Bivalves and gastropods in Cretaceous fossils achieved characteristic range sizes early in their history, and this changed little thereafter. In this group, locally endemic species have much higher chances of extinction than more cosmopolitan genera.

The Present: A Full-Fledged Mass Extinction

There are very few documented cases of extinction of lower organisms. This is an inevitable consequence of our ignorance of the degree of biodiversity of those groups. Consequently, it is not surprising that their current rate of extinction can only be roughly guessed. It is extremely probable that the rate of recent extinctions is several magnitudes higher than the 'background extinction rates' and probably surpasses any similar mass extinction events in the Earth's history.

Among the comparatively well-studied birds and mammals, the documented extinctions in the twentieth century numbers about 100 species. There are a total of 14,000 species of these classes, so the documented extinction rate in this century is about 1%. This translates to an expected average life span of a bird or mammal species of around 10,000 years. This is 100–1000 times shorter than the average life span calculated from the fossil record.

Three different methods for predicting impending extinction rates suggest future life spans of birds and mammals of 200–400 years if current trends continue. These impending extinction rates are at least 10,000 times higher than background rates in the fossil record.

All evidence suggests that a sixth mass extinction event in the history of Earth is underway. While the total effect cannot yet be forecast, we know that the sixth mass extinction will be unique in the Earth's history. It will be the first one resulting not from environmental changes but the extraordinary population growth and the activities of one species. Our species now uses an estimated 25–50% of terrestrial net primary productivity. This is without precedent, and will make the coming extinction qualitatively different from all previous mass extinctions. We know enough to realize the gravity of the problem. We need a more elaborate understanding of the phenomenon, how it affects different groups and geographic locations, as our conservation actions will become more and more critical for the future of life on Earth.

Glossary

Bioinformatics Technology and research aimed at clarifying, coding, organizing, and analyzing biological data through use of computing hardware, software tools, web applications, and theoretical and computational science.

Curation The scholarly study, care, management, documentation, and maintenance of a scientific collection.

Curator A scientist responsible for curation.

Lot A specimen or set of specimens generally stored and studied together, such as individuals of a single species from a single site collected at a single point in time.

Parataxonomist A layperson trained in basic sciences and methods that allow him or her to identify species and higher taxa and conduct biodiversity surveys and inventories.

Phylogeny The evolutionary and kinship relationships of species or the taxa that contain them, usually depicted as branching, tree-like diagrams.

Specimen The whole or a part of an individual organism with a unique data identifier formally added, or accessed, to the institution's collection.

Systematics The study of the evolutionary and kinship relationships of species or the taxa that contain them. Many systematic studies yield results represented by tree diagrams that depict phylogenies (see above).

Type specimen A particular specimen chosen to be the "name bearer" of a species. The characters that diagnose a given species are to be found in the type.

Vouchered specimen A specimen that serves as the basis for extended study and is retained as a reference specimen. A type specimen is a particular vouchered specimen that serves as the basis for taxonomic description and diagnosis of a species. Another example of a vouchered specimen is the one retained as a reference source for tissues used in DNA studies.

Natural history museums (NHMs) and related institutions such as botanical gardens, zoos, and aquaria are devoted to the exploration and study of the biological world, both past and present, and through these efforts provide, with their vast collections, the primary record of life's history and diversity. It has been estimated that some 6700 institutions worldwide serve as the biological repositories for more than 2 billion biological specimens (Duckworth *et al.*, 1993; OECD, 1999; Chapman, 2005; Ariño, 2010). Many of these institutions are also committed to the twin mission of science and education: The research, collecting, curation, and exhibition and educational programs they sponsor serve to enlighten, inspire, and inform a broad public about the richness and wonder of life on earth. In recent decades, these twin missions have taken on a special urgency due to the rapid global degradation and destruction of rain forests, coral reefs, wetlands, and many other natural habitats and the concomitant loss of biological species. That loss, estimated to be at levels 100–1000 times the normal or background rate of extinction recorded in the fossil record (Pimm *et al.*, 1995), constitutes what many biologists call the current biodiversity crisis, an event that possibly could result in loss of anywhere between 30% and 50% of all living species during the twenty-first century, a biological catastrophe approaching the level of the five major mass extinction events in the past 500 million years (Leakey and Lewin, 1996).

Natural history institutions continue to add to their collections and expand on their biological surveys, research, and training. Despite this effort, museum scientists and their colleagues at universities and other institutions still face the enormous challenge of producing a comprehensive census of life's diversity. Between 1.5 and 1.8 million species have been named, described, and classified (May, 1988; Wilson, 2003), but this, by any estimate, is far short of the actual diversity of species living at present. A recognition of our incomplete

knowledge of some highly diverse groups such as insects, and our extremely poor knowledge of many groups of invertebrate animals, fungi, algae, plants, and especially diverse bacteria, protists, and other microbial organisms, suggests that the total number of species could range notably upward from at least 10 million species (Wilson, 2003). The challenge of mustering a better accounting of biodiversity is compounded by the current rate of environmental degradation and the loss of species: Many of these species will doubtless be extinct before scientists have a chance to account for them. Thus the work of NHMs and related institutions is critical to our understanding of both the scope and richness of life and the magnitude of the impacts on the natural world resulting from land degradation and loss, climate change, pollution, invasive species, over-harvesting, and other drivers caused by human activities.

History: The Emergence of Natural History Institutions

The motivations for establishing museums devoted to natural history are deeply rooted in human culture. The desire to observe, contemplate, and memorialize nature is represented in some of the oldest evidence of human thought and expression, including the elegant wall paintings of animals in the 17,000-year-old paintings in the caves of Lascaux. In the less-distant past, the emergence of a place for scientific collections, study, and enlightenment is certainly apparent. Aristotle's "peripatetic school," formally established in 335 BC at the site of the even more ancient Lyceum, was the base camp from which the philosopher and his students roamed the world collecting animals, plants, and other natural objects (Ross, 1995). Aristotle indeed intended to catalogue the whole of life's diversity, a task whose difficulty, as we know in hindsight, far exceeded his enthusiasm for it.

Yet such motivations in the ancients clearly inspired what followed. History is replete with entities that share many of the qualities and objectives of what we recognize currently as NHMs, botanical gardens, and zoological parks. Although such establishments were not, until more recently, characteristic of eastern societies such as those in India and China, their rise and proliferation in western societies coincided with the cultural fruition spawned by the Renaissance that ushered in the Age of Enlightenment. The transition from the seventeenth century inventions of Galileo, including his improvements on the telescope and his design and fabrication of the geometric compass and the thermoscope, to the eighteenth century refinements of the compound microscope, thermometer, and barometer is vividly represented in original collections of the newly renovated and reopened Museo Galileo in Florence.

The European Model for NHMs

Throughout the eighteenth and nineteenth centuries, the great centers for natural history collections were established to provide a home for the specimens avidly collected from the far corners of the world. In most instances, the passions for collecting by wealthy, influential, and in many cases, aristocratic individuals led to the formation of societies or academies devoted to collections and research. Such developments anticipated, sometimes by many years or decades, the actual acquisition of a facility and the attainment of a scientific program adequate to care for such collections (for a review, see [Kohlstadt and Brinkman, 2004](#)). The British Museum, established in 1753, housed (in fact in a private house) the natural history collections that were originally amassed by Sir Hans Sloane, who acquired specimens from many of the British colonies and other parts of the world. Within a few decades, the British Museum could not accommodate the rapidly accumulating collections, a period accompanied by a notorious phase of disarray, where specimens were lost, sold, and even burned in bonfires. Order was imposed by the renowned comparative anatomist and paleontologist Sir Richard Owen, who was appointed superintendant of the natural history departments in 1856. Owen spearheaded the effort to move the collections to a new, appropriately designed building. The resulting grand Romanesque structure, the NHM in South Kensington, opened in 1881. Kew Gardens (or more formally the Royal Botanic Gardens, Kew), established in 1759, grew from the exotic gardens of Lord Capel John of Tewksbury into the world's largest collection of living plants. Some of Kew's most important additions, such as the iron and glass-clad Palm House, came many decades later. Complementing these developments was the establishment of the Oxford University Museum of Natural History in 1860.

Other major museums on the European continent were also established through a prolonged period of gestation. The Muséum national d'Histoire naturelle (MNHN) in Paris was formally founded in 1793 during the French Revolution but was a product of a much earlier, venerable establishment, the Jardin royal des plantes médicinales (Royal Medicinal Plant Garden) created by King Louis XIII in 1635. During much of the eighteenth century the Jardin des plantes was under the directorship of the preeminent naturalist George-Louis

LeClerc, Comte de Buffon. The later-established Muséum national d'Histoire naturelle was also home to such influential scientists as Georges Cuvier, Jean-Baptiste Lamarck, and Geoffrey Saint-Hilaire. The largest NHM in Germany, the Museum für Naturkunde, Berlin, associated with the great eighteenth century German explorer and naturalist Alexander Von Humboldt, was established in 1810, but many of its collections date back to the 1700s. More a product of European, rather than Asian, influences is the Zoological Museum of the Zoological Institute of the Russian Academy of Sciences in St. Petersburg. The Zoological Museum is rooted in developments that took place as far back as 1724 and at present functions as one of the world's largest NHMs.

Museums of the Americas

In the western hemisphere, the transition from naturalists' interest to the formation of societies that ultimately sponsored and promoted the establishment of museums was very much in the European mould ([Kohlstadt and Brinkman, 2004](#)). Indefatigable collecting and a passion for collections led Charles Wilson Peale and his colleagues to ensure that the comparatively young USA had its own NHM. This effort resulted in Philadelphia's Academy of Natural Science, founded in 1812 but not rehoused in a proper building until 1840 (and later in a building opened in 1876). During the 1850s, massive collections of specimens were stored in the Smithsonian's Castle building in Washington, DC but were not transferred to a newly constructed National Museum of Natural History (NMNH) until 1881. Similarly, the American Museum of Natural History (AMNH) in New York founded in 1869 moved in 1877 from its crowded, temporary home in Central Park to a newly constructed, fireproof building adjoining the Park. Soon to follow were the New York Botanical Garden (NYBG) and the Bronx Zoo (later under the management of the Wildlife Conservation Society) opened in 1891 and 1899, respectively, on land purchased from Fordham University.

Beyond the eastern seaboard, institutions sprouted with American expansionism. The Missouri Botanical Garden, St. Louis, the oldest in the USA, was established in 1859 to encompass its ancestral home, the original estate of Henry Shaw, botanist, and philanthropist. The Field Museum in Chicago founded in 1893 first occupied the Palace of Fine Arts, a magnificent structure built as part of the "White City" for the Chicago Columbia Exposition (1893) but one wholly inadequate for housing museum collections. It was not until 1921 that the Field Museum relocated in its present habitat, the massive neoclassical building on Lake Shore Drive. San Francisco's natural history museum, the California Academy of Sciences (CAS), was founded as a society in 1853 and located in a commercial building whose rental income allowed Academy members to build their own facility in 1891. The latter was destroyed in the great fire of 1906 and the Academy moved to its present location in Golden Gate Park. Its facility there was succeeded by a strikingly modern, environmentally friendly, and energy efficient building that opened in 2008.

These institutions were mainly independent entities, meant to mark the cultural attributes of a city or a particular region. Nonetheless, some of the most important natural

history museums and botanical gardens are actually a part of university campuses, including Harvard's Museum of Comparative Zoology (established, 1859), Harvard's Arnold Arboretum (1872), Yale's Peabody Museum (1866), and The University of California at Berkeley Museum of Vertebrate Zoology (1908).

Outside the USA, the roster of North American museums would not be complete without the mention of Mexico's very important Museo de Historia Natural de la Ciudad de México, Mexico City (MNH). Although the newest instantiation of the MNH dates back to only 1964, when it expanded its active research and education programs in biological subjects, this museum's origins can be traced back to 1790, as one of the Americas' first institutions devoted to curatorial research in natural history. At higher latitudes, Canada has had a long commitment to natural institutions. Among the oldest and most prominent of these are the Royal Ontario Museum (ROM) in Toronto, established in 1912, and the Canadian Museum of Nature in Ottawa, launched with the construction in 1912 of a famous gothic revival structure, the Victoria Memorial Museum Building.

This small sample of established museums and related institutions in North America should not exclude other major museums of the western hemisphere. Some of the latter were indeed established concurrently or prior to those mentioned above. Prominent among South American museums are the Bernardino Rivadavia Natural Sciences Museum, Museo Argentino de Ciencias, Buenos Aires (established in 1826, with the first of its current buildings opened in 1929), Museo del Mar, Mar del Plata (1888), Argentina, and the Museu Nacional, Rio de Janeiro, Brazil (1818).

Museums in Africa, Oceania, and Asia

Outside of the Americas, many museums were originally products of colonialism, subsequently reshaped and renovated with new programs after their home countries became independent. Examples include the Nairobi National Museum of Kenya, anticipated by a modest two-room building opened in 1911, moved to the new Coryndon Museum in 1930, and, following the country's independence, renamed and reconceived as the National Museum in 1963, attracting its famous director Richard Leakey in 1968. South Africa has several important natural history institutions that currently carry on very active research, including the Ditsong NMNH (formerly Transvaal Museum) in Pretoria, South Africa, founded in 1892. Other African natural history museums, in various states of modernization and improvement, can be found in Ethiopia, Egypt, Botswana, Tanzania, and Zimbabwe.

In Oceania, the most expansive museums are located in Australia and New Zealand. Australia's oldest, the Australian Museum in Sydney, founded in 1854, currently supports very active research – including new research centers devoted to biodiversity and conservation – as well as collections growth in keeping with Australia's particular emphasis on studying and sustaining its remarkable, and in many cases unique, biodiversity. But that country can claim a number of important institutions, including the Museum Victoria in Melbourne (founded in 1854), the Queensland Museum in Brisbane

(1862) and several others. New Zealand's major institution covering its equally remarkable natural history is the Museum of New Zealand Te Papa Tongarewa, located in Wellington. Its ancestral home was the Colonial Museum founded in 1865, which expanded and moved during subsequent decades culminating in the modern Te Papa that was established in 1992. The Te Papa, which can claim among its arresting exhibits the world's largest specimen of the rare colossal squid (*Mesonychoteuthis hamiltoni*), is particularly notable for integrating themes relating to natural history and biodiversity with the traditions, perspectives, and practices of New Zealand's indigenous peoples.

As noted, Asia historically lacked the longstanding traditions that gave rise to the natural history institutions in Europe, North America, and elsewhere. For example, one of the continent's principal museums, the Beijing Natural History Museum (BMNH), was founded in 1951. Nonetheless, Beijing's museum and many others were direct descendents of China's research institutes established several decades earlier. Indeed, some of Asia's prominent museums, such as the National Museum of Nature and Science in Tokyo, Japan took form as early as 1871. There are a number of other important institutions in Japan as well as other countries that include Israel, India, Malaysia, Pakistan, Philippines, Singapore, South Korea, Taiwan, Thailand, and Jordan. Notable is the growth of relatively new museums as part of the cultural and economic surge in some of the Arab countries. Examples include the Qatar National Museum in Doha and the Sharjah Natural History Museum and Desert Park in the United Arab Emirates.

The Evolution of the Museum Mission

The eighteenth and nineteenth centuries thus marked the emergence and rise of the natural history institutions that still maintain major collections, support active research, and attract tens of millions of annual visitors. Yet the conditions and the premises under which these institutions were originally established were radically different from what they are at present. Although by 1800, the global human population reached 1 billion, the planet still seemed an expansive, mysterious, even intimidating place. Huge areas were poorly known or not known at all. Antarctica, an entire continent larger than Europe and only slightly smaller than South America, was not seen by humans until 1820. Not until well along in the nineteenth century did western scientists encounter, describe, and name the Sumatran rhino, the blue whale, the two living species of tree sloths, the wombat, the pigmy hippo, the spider monkey, and huge numbers of insects and plants. Museums, botanical gardens, and zoos thus sponsored elaborate expeditions to exotic locales, the essence of the so called "Golden Age of Exploration" that marked the 1800s and carried on well into the twentieth century.

Yet even in these early times, museums, explorers, and collectors began to reflect on the diminishing populations of wildlife and the encroachment on natural habitats by people and cities. Several of the great diorama halls, such as the Akeley Gallery of African Mammals in the AMNH in New York that opened in the 1936 (Figure 1), were not only a testament to the grandeur of wildlife but were also intended to

Figure 1 A museum's homage to a vanishing world: The Akeley Hall of African Mammals at The AMNH in New York.

memorialize natural settings destined to disappear in the decades ahead. Museums indeed early on fostered a conservation ethic, one, for example, that embodied the concepts and actions of none other than Theodore Roosevelt, the 26th president of the USA, a Harvard graduate with a strong interest in and knowledge of biology and a life long connection to the AMNH and other like institutions. This legacy of environmentalism set the foundation for the expansive research, educational, and exhibition programs in biodiversity and related themes carried out by present-day museums and other collections-based institutions.

Collections

The organization of institutional collections follows several prescriptions. A fundamental unit is of course the specimen, the whole or a part of an individual organism, living or preserved, fossil or recent, with a unique data identifier formally added, or accessed, to the institution's collection. Specimens vary in completeness and mode of storage according to the nature of the material. A specimen may be a single fossil tooth of an individual dinosaur, a herbarium sheet, a sample of frozen tissue, a pinned butterfly, or each tiny fly in a vial holding hundreds of flies. Specimens are often grouped in a lot, a specimen or set of specimens generally stored and studied together, such as individuals of a single species from a single site collected at a single point in time.

The Size and Scope of Natural History Collections

The accumulated collections of the world's natural history institutions and related biological repositories are of course enormous in size but for a variety of reasons it is difficult to reliably estimate this figure. Collection records vary in

precision from institution to institution and discipline to discipline. Although formal accession records and actual specimens are interchangeable in many herbaria, this is often not the case with zoological collections. Moreover, the very large collections of highly diverse groups such as insects are customarily catalogued with reference to the published literature rather than by individual specimens. Notwithstanding this variation in curatorial methods, total holdings are reasonably well known for some of the major museums (**Figure 2**). Unfortunately, this is not the case for a large number of other institutions, including those in developing countries, where resources for collections-based institutions can be very limited. A mandatory register of biodiversity-related collections does not yet exist.

Well known estimates for total worldwide collections size, primarily in museums, that account for animal, plant, fossil, and mineral specimens range between 2.5 and 3 billion (Duckworth *et al.*, 1993; OECD, 1999; Chapman, 2005). Newer data sources, such as the Global Biodiversity Information Facility (GBIF) (2003), record lower figures, ranging from 407 to 737 million in holdings, but many data rich institutions are not yet members of GBIF. The application of probabilistic and distribution models and case studies to data derived from GBIF and other sources, such as the Biodiversity Collections Index, yields estimates of total worldwide biological collection size ranging between 1.2 and 2.1 billion units, with a unit equaling a single specimen or a group of specimens registered as a single data record and treated as a whole (Ariño, 2010).

Relative biological collection sizes for 10 major museums, which include among them the largest such institutions (**Figure 2**), represent in aggregate more than 426 million biological specimens (both fossil and extant), and thus a large portion of worldwide holdings. With respect to extant species, all of these collections, and those of many other museums, share some of the same characteristics (**Figure 3**). By far the

Figure 2 Total size (in millions of specimens) of biological collections (extant and fossil) of several major natural history museums. Abbreviations are: AMNH, American Museum of Natural History; CAS, California Academy of Sciences; MCZ, Museum of Comparative Zoology; MNHN, Muséum national d'Histoire naturelle; NHM, Natural History Museum; NHM LAC, Natural History Museum, Los Angeles County; NMNH, National Museum of Natural History. Data are from institutional websites accessed November and December, 2011 updated through direct communications with collections personnel at several institutions.

largest portions of collections in terms of numbers of specimens contain insects and other invertebrate groups. This fittingly reflects the vastly greater diversity and abundance of these species in nature, although based on this criterion one might judge most museums as having disproportionately large collections of vertebrates.

In other respects, collections in museums can differ markedly. Thus museums such as the Smithsonian, Field, California Academy, and London have substantial collections of plants, whereas others, such as New York's American Museum, do not (Figure 3). In some cases, this is due to the presence in the same region of sister institutions, such as the NYBG. The latter and other major botanical gardens, such as Missouri Botanical Gardens, Saint Louis, and Kew Gardens, London, combine preserved plant collections (herbarium sheets of plant parts stored in drawers and cabinets) with elegant collections of living plants more familiar to the public. A comparison of collections for some of the major botanical gardens is shown in Figure 4. Zoological parks as well often incorporate notable collections of living plants on their grounds. The San Diego Zoo, for example, is also an officially registered botanical garden, with representatives of more than 6500 plant species.

Most of the figures given above refer to the more traditional collections – namely skins, skeletal elements, shells and other hard parts, whole bodies preserved in alcohol, pinned insects, pressed or living plants, and related specimens. In recent years, a very important new kind of collections has been added to this list. Frozen tissues supercooled in liquid

nitrogen represent a significant new component of collections at certain institutions. Such frozen, or cryogenic, facilities provide tissues highly suitable for sampling deoxyribonucleic acid (DNA), ribonucleic acid (RNA) (where tissues are fresh and rapidly frozen), and proteins. With the proliferation of comparative genetics and genomics at many collections-based institutions, these cryogenic collections have become a core resource for modern collections-based research. Such collections are already substantial and growing at several institutions, including the Museum of Vertebrate Zoology at Berkeley, the Australian Museum in Sydney, the Louisiana Museum of Natural History at LSU, and the AMNH in New York. At AMNH, the cryogenic collection as of 2011 contained 71,000 specimens and is rapidly increasing to fill a facility designed to house more than a million specimens. Other institutions, such as the Smithsonian's NMNH, are launching major efforts to build facilities for this purpose.

Another noteworthy category, culture collections, not typically held by museums and gardens are important resources provided by centers and laboratories specially designed to hold them. Notable here are the American Type Culture Collection and the Provasoli–Guillard National Center for the Culture of Marine Phytoplankton, also in the USA along with satellite collections in developing countries (see also Henderson and Chalmers, 2001). Finally, a few institutions have important seed banks, collections extremely relevant to biodiversity related strategies as they maintain storage for live seeds that can be used to propagate endangered or even plant species recently extinct in the wild. It is estimated

Figure 3 Total size of categories of biological collections (excluding fossils) for several major natural history museums. Abbreviations as in **Figure 2**. Data are from institutional websites accessed November and December, 2011 updated through direct communications with collections personnel at several institutions.

that between 60,000 and 100,000 plant species are threatened or highly endangered (Raven, 1987). Kew Royal Botanic Gardens maintains the world's largest seed bank through The Millennium Seed Bank Partnership (MSBP), a network of partner institutions and researchers across 50 countries. As of 2011, MSBP has successfully banked 10% of the world's wild species with a goal of reaching the 25% mark by 2020. Samples of this collection were used in a striking installation – the “Seed Cathedral” – designed by Heatherwick Studio for the UK Pavilion at the Shanghai World Expo 2010.

Because many museums and gardens are well more than a century old and their collections developed early and rapidly, it might be assumed that current collections growth is eclipsed by that resulting from the initial feverish period of collecting during the “Golden Age of Exploration.” Although the more

charismatic species of large mammals and other vertebrates, many of which are highly endangered, are not routinely collected at present, museum holdings are still growing at an impressive rate. On average, the AMNH, for example acquires more than 90,000 specimens a year – many of them are insects, spiders, and other arthropods – stemming from the work of more than 125 expeditions annually. Other institutions with comparable expeditionary programs show comparable growth.

Collections Digitization and Databasing

One advantage that comes with new collecting is that the incoming specimens are routinely recorded and catalogued into a highly usable digital database. However, retrospective

Figure 3 Continued.

cataloguing of older collections is an immense and expensive task, and there is an intimidating backlog of records awaiting digitization. Of the 1.2–2.1 billion units estimated for total collections worldwide, a mere 3% at most are web-accessible through resources like GBIF (Ariño, 2010). Insects represent a particularly monolithic problem as the international community of specialists have traditionally tied records of these huge collections to published literature rather than on a per specimen or per lot basis, and there are as yet no agreed on standards for retrospective data capture. On other fronts there has been some progress. As of 2011, AMNH New York had completed digitization of approximately 86% of its 3.6 million specimen collection of extant vertebrates, but very low percentages for its insects and other invertebrates. This institution as well as others, including the Smithsonian NMNH,

are also migrating digital records to a single shared platform (at present the KE EMu system), a move that will enhance content management and data exchange within and among institutions.

The continuing progress toward collections digitization is critical in making these resources more accessible and usable, but it has come with some challenges. Prominent among these is the problem of data storage. Simple text and numerical records are for the most part manageable, but very large amounts of digital images of specimens or parts of specimens, especially the high resolution 3D-images and animations based on computed tomography (CT) scans and related resources, are placing very high demands on server storage (Rowe and Frank, 2011). In fact, the terabyte storage requirements for such image-based data now far outstrip those for

Figure 4 Total size of botanical collections in several major natural history museums and botanical gardens. Abbreviations are: MNHN, Muséum national d'Histoire naturelle; NYBG, New York Botanical Garden. Data are from institutional websites accessed November and December, 2011 updated through direct communications with collections personnel at several institutions.

DNA sequence, amino acid, and other types of molecular data. Digital storage now and going forward is a problem facing the whole museum community and it will require a more concerted effort to find solutions by networked institutions both at national and international levels.

Collections Management and Conservation

Notwithstanding new approaches and technologies, the key factor in ensuring the quality and effectiveness of the natural history collections remains the staff responsible for its management, maintenance, conservation, and use. Here the core positions are the curators and collections managers with expertise relevant to a particular area of the collections. Since collections vary considerably not only in the nature of their taxonomic content but also in the means of their storage preservation and organization, they require a diversity of persons with special expertise and skills. Nonetheless, there is a recent trend toward developing a more hierarchical collections management team within a logically defined area of the collections. For example, there may be one or more curators and one or more collections managers for a particular collection, such as birds or mammals. However, the activities of the collections managers for each of the vertebrate groups

can be coordinated by one or more supervising collections managers who report to the various curators responsible for vertebrate collections. Such organization is especially useful where there are shared methodologies and activities, such as the digitization of collections records, the mechanics of loan processing, or the protocol for delivering material for common frozen tissue collections.

Another important function that can be applied across many disciplines and collections is the one involving preparation and conservation of specimens. In recent years, there has been an increase in focus on natural history collections and the special problems they pose for conservation and risk management. This has promoted development of storage facilities that are more temperature- and humidity-controlled and are more effectively sealed from invasion by insect pests. Techniques that call for integrated pest management, involving specimen preservation and optimal cabinetry design are better and safer alternatives to the older and now diminishing use of par-Dichlorobenzene (p-DCBs) and other problematic chemicals to control pests. The First World Congress on the Preservation and Conservation of Natural History Collections held in Madrid in 1993 catalyzed an increase of published studies and activities by such organizations as the Society for the Preservation of Natural History Collections, now in its 27th year.

Museum Research: Its Role in Understanding Biodiversity

Taxonomy and Systematics

Natural history collections of the world, both large and small, comprise the source for the basic science that provides the essential information on present and past biological diversity. Newly discovered species are named and described as part of the discipline of taxonomy, and their evolutionary relationships with other known species are identified in the approach known as systematics. At present, systematic biologists base their studies on genomic data (arrays of genes or whole genomes) and phenomic data (features extrinsic to the genome that include proteins, cell structure, anatomy, and many other characters). Such research leads to the development of phylogenies, tree-like maps that depict the branching relationships of species and higher taxa, and the establishment of biological classifications that array living and fossil species into formally named, more inclusive groups. Natural history museums, botanical gardens, and related institutions represent the greatest concentrations of experts devoted to taxonomy and systematics. Such work and other museum efforts in fields such as biogeography, climate study, paleontology, geology, ecology, molecular biology, and conservation biology provide an important scientific foundation for efforts to conserve and manage biodiversity and contribute to a wide range of applications in animal and human health, agriculture, pharmaceuticals, bioprospecting, resource management, and government policy and practice.

A key practice in taxonomy is the establishment of a type, a particular specimen chosen to be the “name bearer” of a species. The characters that diagnose a given species are to be found in the type. Taxonomy involves a considerable amount of revision, wherein a named species may be found to be indistinguishable from an earlier named species by comparing the types of the two species. Conversely, a new species may be recognized or “split off” from what was once regarded as only a single species because one or more of the specimens referred to the original type show significant differences. The new species will then have its own new type specimen. Such types are extremely important components of any collection. Sometimes even smaller museum collections can be very important resources because they hold a very large number of types relative to the total number of specimens in the collection. Moreover, type collections are often provided special high security locations and are subject to more stringent or even restrictive loan policies.

Another class of specimens important for collections-based research is a vouchered specimen, namely one chosen as the basis for extended study and retained as a reference specimen. A type specimen is a particular vouchered specimen that serves as the basis for taxonomic description and diagnosis of a species. Another example of a vouchered specimen is one retained as a reference source for tissues used in DNA studies. A vouchered specimen may also be one chosen to denote the occurrence of a particular species in a particular geographic locality. Thus, museums provide an important service in housing vouchered specimens for various purposes and are critical to areas such as comparative genetics, biodiversity surveys, and conservation biology.

Genetic, Genomic, and Phenomic Research

Traditionally, specimens and the species they represent have been described and diagnosed on their extrinsic characters – the leaf venation of plants, aspects of internal and external skeletons, hair and feather color, scale number, size and shape measurements, and other features of great variety. For some decades, studies at the molecular level have played an increasing role. Molecular systematics came into play when genetic data could be used to separate groups of individuals or local populations belonging to one species that could not be distinguished by their extrinsic characters. These sibling species, or cryptic species, are thus only distinguishable at the genetic level. A later development is the use of DNA barcoding, wherein slight differences in the order of sequences in a single gene or a few genes are the basis for recognizing different local populations, subspecies, or species (Hebert *et al.*, 2004). DNA barcoding relies on genes with an apparently rapid mutation rate, such as the mitochondrial gene cytochrome *c* oxidase I in animals and chloroplast genes *rbcl* and *matk* in plants. Such genes show high variability even among closely related species. DNA barcoding has been widely adapted and is often applied to the recognition of new species that warrant protection as a conservation priority. Barcoding as well has other conservation uses, such as in identifying the source of illegally transported items such as rhino horn, elephant ivory, or tiger paws, or the true species used as a source for commercial products like lumber, caviar, and tuna. Several museums foster programs that are active in DNA barcoding and its applications.

Genetic approaches, such as DNA barcoding, have been criticized as overly reliant on such a small unit of the entire genome for drawing important taxonomic decisions (Tautz *et al.*, 2003). Earlier phylogenetic studies that relied on DNA sequencing also faced similar criticisms because they accounted for only a few genes out of the tens of thousands of genes in any given genome. The dramatic technological improvements in high throughput DNA sequencing have, however, obviated some of these issues. The cost and time necessary for sequencing large portions of the genome and even whole genomes has decreased dramatically in only the 10 years since the publication of the first sequence of the human genome in 2001 accomplished at costs greater than \$100 million (Metzker, 2010). As of June 2011, it was possible to sequence the human genome comprising 25,000 protein-coding genes and 3 billion nucleotide bases for \$10,000 in direct costs (Wetterstrand, 2011 National Human Genome Research Institute (NHGRI) website). It is conceivable that in the near future whole genome sequencing will become so automated, efficient, and inexpensive that many museum specimens will be routinely sequenced in this way. In the meantime, most of the current phylogenetic studies on more complex organisms, such as animals and plants, with larger genomes (10–100 billion base pairs) are being carried out at subgenomic levels. For example, a recent study of mammalian phylogeny compared sequences of 26 gene fragments in 164 living mammal species and five vertebrate species outside mammals (out-groups) using newly generated sequence data and the gene libraries available in the international repository GenBank (Meredith *et al.*, 2011).

Another molecular approach allows the sampling of a far greater number of genes by sequencing the RNA that transcribes the sequences of genes that code for proteins (Wang *et al.*, 2009). This transcriptome method can yield patterns that represent thousands of genes, but it does not provide precise maps of the actual base pair sequences of particular genes that one can identify when sequencing whole genomes. Moreover, sampling and sequencing RNA require very fresh, high quality material that exceeds the preservation standards usually found in museum collections and even earlier collected specimens in frozen tissue facilities. This requirement places a premium on careful collecting, rapid freezing and preservation, and a well-curated tissue repository. However, one great advantage of whole genome sequencing, when it becomes even more readily accomplished at lower cost, is that it can also be used on material that has been preserved in collections for decades, such as feathers, hair, skins, and even fossils (Green *et al.*, 2010). Many collections-based institutions, such as NYBG and AMNH, New York; The Field, Chicago; NHM, London; CAS, San Francisco; NMNH, Washington, DC; and MNHN, Paris now have laboratory facilities and active programs in comparative genetics, and some of these (e.g., AMNH) are even sequencing whole genomes of less complex organisms, such as bacteria.

The increase of genetic and genomic research in museums has not diminished the importance of phenomic research at these institutions. Indeed, the museum expertise that combines a deep knowledge of natural history, basic taxonomy, comparative anatomy, and histology with genetic approaches offers powerful insights to major questions that deal with the organization and evolution of biodiversity. A much clearer understanding of the relationship of the genome to the phenome remains a central goal of all biology, and museum scientists have and will continue to play a key role in this quest. Modern comparative phenomics, such as the study of very detailed aspects of anatomy and tissue structure, is greatly aided by powerful imaging and software tools, such as CT-scanners, confocal microscopes, and 3D-digital reconstruction and animation. Such new technology is now readily being used to study fossils, the overwhelming majority of which are inaccessible to DNA sampling. Some museums now support state-of-the-art imaging laboratories to carry on such important research.

Technology and research activity has produced a huge influx of both genomic and phenomic information – a data deluge – which places an enormous burden on the effort to clarify, code, organize, and analyze these data. Thus, museums are committing major resources to the development of on-site and collaborative bioinformatics. Such programs generally comprise three components: (1) computing hardware infrastructure, such as facilities for cluster computing; (2) software tools and web applications for organizing databases, developing data pipelines for processing information, and providing visualizations; and (3) theoretical and computational research reliant on high-end computing, discrete math, and algorithmics. Examples of projects that rely heavily on advanced bioinformatics and involve museum and botanical garden science include a comprehensive study by the New York Plant Genomics Consortium (NYBG, AMNH, Cold Spring Harbor, and New York University) of 150 different species of plants based on 23,000 sets of genes that code for

certain proteins. Using powerful databasing and computation tools, these gene data were grouped, ordered, and organized into a phylogenetic tree representing the evolutionary relationships of the plant species (Lee *et al.*, 2011).

On the phenomics side, diverse and complex character information can now be interactively and simultaneously loaded into very large matrices incorporating images, labels, comments, and literature citations through powerful cloud-computing web applications. One such application, MorphoBank, (O’Leary and Kaufman, 2011) is currently the home site for more than 100 published and 383 ongoing projects. MorphoBank is being used for one of the largest phenomics projects ever launched, an investigation supported by the National Science Foundation-sponsored Assembling the Tree of Life project for living and fossil mammals, which has produced a matrix with 4500 characters from the skeleton, dentition, and soft anatomy in a large number of species (Novacek and The Mammal ATOL Team, 2008). The resultant matrix, which incorporates nearly 450,000 labeled images, was developed by 22 international investigators from nine institutions, including four museums.

The development of such bioinformatics capacity will be vital to collections-based institutions going forward. Comparative biological data relating to museum research are among the most complex in any science. The supersized data matrices like those noted above, require sophisticated computational programs for tree construction and other operations. Such complex data require a heuristic approach to achieving resolution among an astronomical number of possible trees (more than 2 million for a data set with only 10 taxa and 4.5×10^{190} for 100 taxa). For this reason some museums have developed research areas that encompass theoretical computational biology in addition to other areas in bioinformatics.

Biogeographic and Environmental Studies

In addition to taxonomy, systematics, genomics, and phenomics, museum research extends into other areas that rely on complex data to address questions important to understanding biodiversity. One of the most notable of these endeavors is the application of Geographic Information Systems, using satellite-based imagery and other means to assess the distribution of species in relation to various environmental parameters, such as climate conditions, topography, vegetation cover, and proximity to cities or other sites of human occupation. Some of these studies incorporate sophisticated computational tools that allow investigators to predict the occurrence of particular species in areas yet unexplored for them by analyzing the multidimensional parameters that are consistently present at localities where these species are known to occur. These analyses then can be applied to assessments of conservation priorities in regions, such as Madagascar, experiencing widespread habitat destruction (Kremen *et al.*, 2008). Other approaches model changes in the range, density, and diversity for groups of species under different likely scenarios for climate change in a given region, such as the critical studies of vulnerable Fynbos flora of southern Africa (Midgley and Miller, 2005). The application of such approaches to informing conservation strategies and policies has and will continue to be critical.

Biodiversity: The Need for a Better Census of Life

The aforementioned research areas underscore the importance of museums and like institutions in our effort to understand the vast array of species that occupy the planet. Museum scientists represent a large proportion of working systematists who deal with the description of the basic units of biodiversity, namely species, and place them in an evolutionary context by mapping the relationships of those species and their higher groups within phylogenies. Other aspects of museum research in biodiversity concern the geographic distribution of species as a function of various environmental factors, as well as the study of life cycles and ecological relationships.

Yet we are still confronted with the challenge to more fully account for such diversity, and demonstrate how it is impacted by the global scale environmental changes in play. As noted above, the 1.8 million species named do not, within orders of magnitude, capture the true number, which may be in the order of 10 million or more species yet to be identified (Wilson, 2003). Insects alone represent a staggering amount of known and unknown diversity with 800,000 species named, and doubtless millions more to discover. Approximately 100,000 fungi have been described and named, but this group is thought to number more than 1.5 million species. In terms of sheer biomass, the various worm groups, including segmented annelids and unsegmented nematodes, may represent four out of every five animals on Earth. Approximately 15,000 nematode species have been named and the existence of millions more is suspected. An even more profound void in the census of life concerns bacteria and related microbial species, the oldest, most ubiquitous, most rapidly evolving, most physiologically diverse, and most poorly known of all organisms. Only approximately 6000 species of bacteria are recognized, but estimates of true diversity in the soil and the water columns using DNA probes and other methods indicate the presence of many millions of species (Gans *et al.*, 2005).

It is clear that the great collections and active research programs in museums and botanical gardens, and other collections-based institutions underrepresent the true diversity of such important groups as terrestrial arthropods, marine invertebrates, fungi, and microbial bacteria and protists. Indeed, specialists on certain of these groups are either nonexistent or a very few of the already insufficient number of some 6000 taxonomists worldwide (Wilson, 2003). There has been a welcome and recent introduction of microbial programs in a few museums, but this area is due much more emphasis as museums consider options and opportunities for future expansion of their collections and research. In addition, there is further need to integrate basic information of species diversity with other biological phenomena, such as population patterns, nutrient cycling, and resource partitioning, in order to demonstrate the important ecological roles of species within biological communities. Such more integrative research requires a scale-up in multidisciplinary approaches involving numbers of museum investigators and colleagues at other institutions.

Biodiversity Science and Conservation

Museums and other collections-based institutions have taken a number of different approaches in responding to the

urgency and magnitude of the biodiversity and other environmental crises. Recruitment of curators to leadership scientific positions in some cases has emphasized the need for coverage of poorly known biological groups, or for expertise that relates basic biodiversity knowledge to experience in bioprospecting, surveys, environmental trend analysis, and related approaches. Many institutions have also developed special centers devoted to biodiversity science and conservation biology and programs. These units are meant to initiate programs more connective to the needs of local communities and governments by providing current, accurate, and relevant information on biodiversity and other impacts on the habitats in question. They also help in organizing large scale interdisciplinary projects, such as surveys that enlist teams of experts on diverse taxa and produce results that are of use in setting policy for the management of natural areas and habitats under threat.

It is clear that such scaled-up efforts in surveys and inventories are much needed. Many species now known to science have yet to be sufficiently sampled for their genetic composition. Large areas of the planet, such as the mid ocean, deep sea, and polar regions have barely been explored. There are hundreds of sites and regions throughout the world now considered under high threat or endangerment that contain a large diversity of endemic species, namely, species that are found nowhere else outside of the region in question (Sala *et al.*, 2000). Such highly vulnerable regions include most of Madagascar, the floral communities of southern Africa, Mediterranean coastal habitats, many coral reefs, high-latitude deserts, and montane forests of the Andes, Himalayas, and other ranges (Sala *et al.*, 2005). The identification of such regions and their endemics is the direct result of taxonomic and biogeographic research, much of it museum based. These areas, sometimes referred to as biodiversity hotspots (Myers *et al.*, 2000), help to define the ongoing and future agenda for biodiversity science and conservation.

Museum Advisory Roles and Applications in Biodiversity Conservation

Basic information stemming from surveys and collections is important in informing much broader constituencies about biodiversity loss and thus underscoring the need for mitigation and more effective conservation management. Vouchered specimens from collections serve as keys and references to field experts and parataxonomists in identifying the specimens or in assessing the impact of environmental degradation on animal and plant populations. Web-based publications such as the International Union for the Conservation of Nature's (IUCN's) Red Lists of Threatened Species are to a large part reliant on information from museum-sponsored field surveys and collections (see also Henderson and Chalmers, 2001). The ongoing digitization effort for large collections is an important advance that provides more ready access of information to conservation practitioners and land managers.

Such programs may also link to private or government agencies that manage biodiversity (Henderson and Chalmers, 2001). The latter include the Environmental Resources Information Network in Australia, the National Commission for

the Knowledge and Use of Biodiversity (La Comisión Nacional Para El Conocimiento Y Uso de la Biodiversidad) in Mexico, and the National Biodiversity Institute (Instituto Nacional de Biodiversidad; INBio) in Costa Rica. INBio was established as an initiative with a particular emphasis on biodiversity science and conservation across a broad range of activities, from maintaining collections, conducting bioprospecting, and training parataxonomists, to educating the public on the importance of biodiversity resources. Collections- and field-based institutions also serve many other needs relating to biodiversity conservation (Henderson and Chalmers, 2001). They deliver scientific information bearing on the regulation of import and export of biological species, many of which present both environmental and health hazards in areas where they are artificially introduced. They also provide data vital to the development of international treaties and conventions meant to protect species, such as The Convention on International Trade in Endangered Species (CITES). And they play a prominent role in resource management. Accurate identification of species is necessary in developing effective pest management and programs for management of such commercial activities as agriculture, fishing, and domestic breeding. The increased trend toward local farming, green markets, and farmland that embraces a combination of cultivated and natural habitats (Foley *et al.*, 2005) relies on information of local and highly beneficial biodiversity, such as wild species of pollinating bees. Surveys by taxonomic experts disclose biodiversity and population changes before and after high impact industrial projects, such as mining or oil exploration or industrial-induced environmental disasters.

A more formal extension of such activities is the Museum service as a source for recommendations and advice on policy and practice relating to biodiversity loss and other environmental issues. Here the institutions must distinguish their mission as the providers of recommendations based on sound scientific results from that of various advocacy groups that may use such information for various purposes. In this way, the reputation of museums as trusted guides and the impact of the scientific work they foster are assured. Museums and like institutions provide the fundamental data on the realities of habitat degradation and its biological affects due to urban sprawl, deforestation, mining, war, and other human activities. Some countries, such as Australia, require biodiversity surveys and impact studies before any development is approved, and both impact studies and remediation programs are required by many local authorities in many countries.

At the government level, Museums have and will continue to play a critical role in both the development and implementation of policy. The effectiveness of the CITES treaty, for example, requires the continued contributions of accurate identifications and assessments supported by museums and like institutions. Museums are also important participants in developing initiatives prescribed by the Convention on Biological Diversity (CBD), and official delegations of the CBD, the IUCN, and many other international organizations and conventions include museum scientists and staff (Henderson and Chalmers, 2001). Implementation here is aided again by museum-based programs that offer training of in-country expertise in biodiversity sciences.

Applications in Human Health and Other Areas

Museum-based research on biodiversity also has applications that extend to other areas such as health and commerce. Studies by museum scientists and collaborators on the evolution of *Plasmodium*, the microbial parasite responsible for malaria in humans and other species, is contributing to our effort to understand better the nature and effects of the world's deadliest infectious disease (Perkins, 2008). Other insights by comparative biologists are important for forecasting the spread of viral epidemics, managing conditions for the prevention of diseases like cholera and typhus, and finding relationships between environmental degradation and likelihood of disease outbreak promoted by opportunistic species. Importantly, the comparative approach used by most museum scientists to investigate problems in biomedicine and health moves beyond a focus on standard model organisms – such as the fruit fly, mouse, or the bacterium *Escherichia coli* – and instead relies on the 3.6 billion-year-old experiment that is integral to the evolution of all life. Such a comparative approach may lead to insights that allow the mapping of convergent evolution of certain diseases, such as human papillomavirus (Chen *et al.*, 2009) or the variations evolved in blood anticoagulants (Phillips and Siddall, 2005). A classic study by Pershing *et al.* (1990) disclosed the potential for the spirochete *Borrelia burgdorferi* infection before the recognition of Lyme disease as a clinical entity by sampling museum specimens of the deer tick *Ixodes dammini* for the presence of spirochete-specific DNA sequences. The latter sequences were detected in 1940s specimens from Montauk Point and Hither Hills, Long Island, New York. These results suggested that the Lyme disease spirochete was already active in arthropod vectors for at least a generation before the formal recognition of this disease in the USA. Bioprospecting continues to produce discoveries important to pointing the way to new pharmaceuticals or food sources. In fact, the recent burgeoning interest in wild species of plants, fungi, insects, marine invertebrates, and other organisms as sources for healthy, and in some cases gourmet foods, reflects an appreciation for the potential bounty of biodiversity and the scientific information required for utilizing it.

Biodiversity and Culture

Noteworthy also is the knowledge of biodiversity as an inroad to understand the relationship among different cultures and societal traditions. The common formal taxonomy for species names and their classification, which is currently used in virtually all scientific literature, is actually an European development attributed to the work of the great eighteenth century Swedish naturalist Carolus Linnaeus, but some form of “folk” taxonomy has emerged from virtually every region and culture. We know that many people have developed traditional skills and languages for identifying species, and their success at this practice is impressive. Certain tribes in the Amazon are familiar with thousands of species, many of them important as sources for foods and medicines; outsiders have learned much from these great native naturalists. A study by a research team including museum scientists (Fleck *et al.*, 2002) examined the folk taxonomy of bat species used by the Matsigenka Indians in

Amazonian Peru and found it surprisingly comprehensive. Although Matses have only one name for all bats, cuesban, they use descriptive terms to distinguish 43 different bats. Of the 57 species collected by scientists in the area over the years, 34 species had also been hunted by Matses, whose notebooks provided previously unknown information on the roosting habits of several of them. Moreover, at least 14 Matses names closely correspond to standard Linnaean taxonomic names.

This is only one of numerous examples where knowledge of local cultures demonstrates a shared interest and understanding of nature, a common attitude extremely important in developing practices for the sustainability of local species and habitats. Accordingly, staffs at some museums include anthropology curators with specific interests in the ways in which different cultures recognize and use biodiversity as integral to their traditional practices and everyday lives. Biodiversity training programs that take into account local traditions and perspectives are also offered by museum-based biodiversity and conservation centers.

Current Challenges

Despite the clear linkage among collections-based biodiversity science and conservation, human health, and other areas of societal need, there are many challenges to the effort to strengthen this connection. As noted, there is still a deficit in the number of experts, particularly for some of the groups least known and potentially most important for ecosystem services such as microbial organisms, fungi, and pollinating insects. The possible training programs for developing such expertise at universities, museums, and other institutions are limited in number. Even at the broadest levels, the uneven distribution of expertise and collections resources impedes efforts to account for biodiversity on a global scale. Much of the world's biodiversity is located in economically depressed countries very poorly endowed with relevant expertise and scientific infrastructure (Argawal and Redford, 2006). Thus, international programs for in-country training of local people are among some of the most needed and effective programs sponsored by museum-based biodiversity centers and similar organizations.

Results of biological surveys and prescriptions for the implementation of locally- or nationally- directed conservation management are often insensitive to local concerns relating to particular levels of education, economic background, cultural affiliations, and religious beliefs. People in developing countries are, for instance, faced with difficult choices because of their very poor standard of living (Argawal and Redford, 2006). Development of recommendations and programs more sensitive to these factors yields a more effective and feasible strategy for sustaining local natural resources, and is also key to identifying some of the overarching concerns shared by many different communities and cultures.

In the end, the reliable data and results of biodiversity surveys and research may have a less than desired impact in some instances simply because decision-makers and their constituencies fail to recognize biodiversity sustainability and management as a priority need. In many cases, this lack of

attention seems rooted in a poor understanding of the fact that biodiversity loss is not a completely isolated issue, but one that bears on the economic, health, and quality of life issues that demand so much attention (Novacek, 2008). Hence, biodiversity research, surveys, and recommendations for conservation must be closely linked with educational efforts at many levels, a point expanded further below.

Training, Education, and Outreach

Graduate and Postdoctoral Training

Museums and the like are in reality major centers not only for research but also for training in the sciences concerned with biodiversity, such as taxonomy, systematics, evolutionary biology, biogeography, and conservation biology. Their increasing role in this respect relates to particular trends in higher education, where much of the training in these fields was displaced at universities by other areas, such as biomedical research, experimental neurobiology, and genomics centered on model organisms. In more recent years, the evolution of these disciplines has come full circle – the flood of technology offered by genomics and computational biology has been readily adopted and expanded on by researchers devoted to field work, collections, and the natural sciences. At the same time, there has been a rebirth at some universities of programs in evolutionary and organismic biology that draw more emphatically on the kind of expertise normally found in museums. A continuing trend in this convergent effort in research and training among universities, museums, and other collections-based institutions offers increased opportunity for the cultivation of biodiversity expertise.

Many museums and botanical gardens for example participate in joint programs with universities in the graduate training of new generations of scientists. Prominent among these are AMNH and NYBG (with Columbia, Cornell, New York University, and the City University of New York), the Smithsonian's NMNH (with George Washington University), the Field Museum (with the University of Chicago), and San Francisco's CAS (with University of California at Berkeley and Stanford University). Many of these arrangements involve a cost share for the graduate program, the advisory role of curators who are also adjunct faculty at the partnering university, and the eventual bestowal on the successful candidate of a PhD degree by the university involved. A more independent role for museums in graduate training is represented by the establishment in 2008 of a PhD program in comparative biology in the Gilder Graduate School at the AMNH. Thus the AMNH joins the Paris MNHN as the only independent museums in the world that offer a PhD degree.

At more advanced training levels, there are numerous postdoctoral programs that support scientists at museums concerned with biodiversity. Some of these incorporate international postdoctoral and graduate level training in order to develop the level of in-country expertise necessary for the global effort. Still, the number of programs and opportunities available in museums and in joint museum-university programs are limited and are far outstripped by the current demand for them by talented, well-educated students.

Student and Teacher Training

Museums of course have a much broader educational agenda than that concerned with graduate and postdoctoral training. These and related institutions intersect daily with vast audiences – families, school children, senior citizens, and other individuals from diverse cultural and economic backgrounds. Much of the investment by museums and related institutions in education involves better ways to serve the millions of students in classes from primary and secondary schools that visit museums each year. Many museums are now tied to school curricula and are timed to intersect with course work in general biology and related fields. After-school programs offer opportunities for field trips and laboratory activities not readily available in classrooms. Much educational learning is greatly aided by digital offerings on the web and software applications that allow students to prepare for museum visits and assemble information after they return to the classroom. Several cities have also developed cooperative educational programs in biodiversity and other subjects that link museums, gardens, zoos, and related institutions in the region as an educational resource for both teachers and students. For example, the Urban Advantage program in New York City is a standards-based partnership designed to improve students' understanding of scientific inquiry through collaborations between urban public schools and science cultural institutions with AMNH as the lead institution, and including NYBG, the Bronx Zoo, the Brooklyn Botanical Garden, and others. Urban Advantage has now been adapted in other cities, including Boston, Miami, and Denver.

Eliciting Public Understanding and Engagement

Beyond advanced academic training and school programs, museums, botanical gardens, and related institutions have a unique connection with a vast public audience. Even in more economically and technologically advanced countries, there are limited opportunities for the lay public to stay abreast of the rapid rate of scientific discovery (Falk *et al.*, 2007). Outside popular science books, periodicals, films, television specials, and web offerings, the responsibility for providing a lifelong exposure to science falls to museums, botanical gardens, zoos, aquaria, science centers, and similar venues devoted to the public education of science.

These institutions are thus critically important in educating people on biodiversity issues and other environmental problems. However, in doing so they confront some major challenges. A consistent result in surveys of public attitudes, such as the Biodiversity Roadmap Report of 1998, is that the basic message – that the biodiversity enormously important to the sustainability of the environment and the quality of our own lives is at serious risk – is not getting across to many of the target audiences. The most penetrating messages are those that clearly relate scientific insights concerning biodiversity and biodiversity loss to more general environmental problems and in turn to problems rooted in common experience – poor water quality, depletion of fisheries, zebra mussels and other invasive species, forest clearing, open pit mining, urban sprawl, and many others. Basic biodiversity science of course provides the important database for all these arguments. But

the public recognition of the importance of this work is elusive without the themes that address more familiar issues (Novacek, 2008).

One bridge that must be crossed in connecting biodiversity science with a diverse public is in inspiring a closer interest in and affinity with nature. The fact that museums and like institutions can offer an encounter with nature that is both vivid and authentic defines their cultural impact (Novacek, 2001). Many people, especially in urban areas, will rarely, if ever, see a relatively unspoiled tract of woodland in their region, let alone a tropical rainforest. For these individuals, an encounter with nature means a visit to a museum or the like. The enthusiastic response of visitors to this opportunity can be appreciated in terms of the huge audiences such institutions attract. Attendance figures for 2010 provided on the websites of just 18 museums, botanical gardens, zoos, and aquaria, including some of those shown in Figures 1 and 2, numbered more than 44 million visitors. Another survey claimed that more than 865 million people visited museums, gardens, zoos, nature centers, science centers, and related venues in 1999 in the USA alone (Lake and Perry and Associates, 2001). An additional attribute of museums and institutions as venues for communicating science is the feeling of trust they invoke in the public. Surveys show that natural history and science museums have extremely high credibility ratings (Lake and Perry and Associates, 2001).

The Impact of Exhibits

Notwithstanding the many educational programs offered by museums and like institutions, the primary “flagship” vehicle for connecting with the public has always been and continues to be exhibitions. The accuracy, currency, and inspirational qualities of such exhibits of course reaffirm the museum's role as a powerful source of public education and enlightenment. Yet, on the biodiversity front, there was a period of educational stasis; such institutions had not fully capitalized on their reputation as trusted guides. During the early 1990s, when dimensions of the biodiversity crisis became more evident, very little of the scientific concern was reflected in public exhibits. Many permanent exhibits that included environmental topics had not been revised since the time they first opened decades before, or were not complemented by new halls or temporary exhibits that addressed current themes (Novacek, 2001).

Part of the reason for such arrested development was doubtless financial. Renovating exhibit halls or building new ones are massive and extremely expensive endeavors, and there are often major economic constraints to progress. Despite the challenge, there are more recent notable improvements on this front, and exhibits dealing with current environmental issues, including biodiversity, have been developed by many museums and related institutions. The AMNH in New York was one of the first, if not the first, to open in 1998 a major permanent Hall of Biodiversity. The exhibit is meant not only to inform the public on the stark realities of global species loss and the biodiversity crisis but also to show the beauty, wonder, and diversity of what is at risk. Its features include an electronic “BioBulletin” presenting

regularly updated accounts of events that impact biodiversity and scientific and conservation efforts to mitigate these impacts, in places like Madagascar, Bolivia, the Congo, and Mongolia. The exhibit also has a walkthrough diorama of a section of rain forest of the Central African Republic that shows the impact of human activity on even a relatively pristine environment. The diversity of life in the hall is covered by the “wall of life,” that displays more than 1500 specimens and models complemented by videos of organisms in action and interactive touch screens. The wall of life has proven to be one of the museum’s most popular attractions. A completely renovated Milstein Hall of Ocean Life incorporating many environmental themes and adjoining the Hall of Biodiversity reopened in 2003.

Elsewhere, exhibitions devoted to more current environmental issues have been developed at various scales. At the ambitious end of the spectrum, the CAS reopened in 2008 in an entirely new structure devoted to collections, research, and exhibition halls, including many exhibits with a strong environmental emphasis. The new museum is itself one of the largest high grade, green buildings in the USA (Barinaga, 2004). London Natural History Museum’s new Darwin Center is a bold statement that reveals its massive collections and its laboratories to visitors within an evocative seven-story, concrete “cocoon” encased in a huge glass-walled “cube.” The Darwin Center thus brings the public more in contact with the kind of biodiversity- and collections-based research that is usually “behind the walls.” Complementing the magnificent Grande Galerie de l’Evolution at the Museum National d’Histoire Naturelle in Paris are a series of temporary exhibits that explore the wonders of biodiversity and the mysteries of oceanic life, such as its recent exhibit “The Deep,” which subsequently traveled to other venues. There are other similar installations at the Smithsonian’s NMNH, the Field Museum, the Denver Museum of Nature and Science, and others too numerous to describe here. Also, new partnerships among institutions have allowed the sponsorship and nuanced development of timely exhibits on such themes as endangered species, climate change, the importance of evolution in understanding biodiversity, and issues regarding the present and future availability of fresh, clean water. These and other exhibits with similar themes offer clear and consistent messages as they travel to various international destinations.

Public Educational Programs and Citizen Science

Although exhibition remains the principal educational portal and indeed the prime visitor attraction in museums, there has been an increasing emphasis on educational programming either connected to or independent of exhibits. Much of this relates to the programs noted above that link to school programs for teacher and student training and are designed to complement approved curricula. In addition, museums and like institutions are demonstrably very effective locations for major conferences on subjects of high public interest. Several aforementioned institutions sponsor annual symposia on biodiversity issues that include public lectures and panel discussions and the proceedings are now very often webcast in order to reach very large online audiences. Museum scientists

are heavily featured in many media offerings including television specials, newspaper articles, and online blogs. For example, a recent feature of the New York Times, “Notes from the Field” provides daily journals from field scientists conducting biodiversity surveys and similar studies in remote regions. Another increasingly common feature of museums, are “Science Cafes,” regular evening informal gatherings aimed at young adult audiences, wherein scientists share their adventures, results, and thoughts over cocktails.

These programs and many others are largely built on a strategy of engagement that allows educators to share information and perspectives, and elicit reactions in terms of questions and discussion. What about more active roles on the part of public audiences? A relatively new educational effort aimed at eliciting broader public engagement – dubbed citizen science – involves public-professional partnerships that allow people of all ages an opportunity to participate in real scientific research and to interact with scientists in the process (Cohen, 1997; Brossard *et al.*, 2005). This kind of proactive participation is intended to not only contribute new data on species and habitats but will also increase the participants’ understanding of the process and results of the relevant science (Tuss, 1996). Such enlightenment is further hoped to strengthen participants’ connections with both science and the environment in ways that cultivate a sense of stewardship.

Citizen science programs require intensive investment of professional time and energy, and, to date, the number of people that actually have the opportunity to become citizen scientists is limited. The problem seems surmountable as more efficient programs, including the use of social networking and web-based technology for linking scientists with science educators and their students, become available. The Bioblitz (2007) biodiversity surveys that have been carried out in New York’s Central Park, Washington, DC, and many other sites yielded new scientific results that not only further enthused participants and galvanized their activities but also attracted media interest. It seems that programs in citizen science have much potential if they allow more people to participate, their impacts are more thoroughly analyzed, and participants are given a more explicit presentation of the environmental issues that relate to their contribution (Brossard *et al.*, 2005).

Conclusions: Museums and the Biodiversity Challenge

Many major museums and related institutions of the present day have histories extending back well nearly two centuries. Yet these institutions are arguably more important than ever, as we contend with the dramatic environmental transformation of this planet in this century. There is an exciting and unprecedented opportunity for museum researchers to participate in and even lead the great quest to account much better for the great scope of biodiversity and the organization and evolution of life.

There are of course many challenges to the enterprise. On the science front, the lack of taxonomic expertise in many areas, the uneven distribution of scientific personnel and

resources globally, and the huge expenses and investment in time necessary for collecting, organizing, and digitizing collections information are all impediments. On the educational front, the low level of science literacy coupled with public indifference or even resistance are also major obstacles. A very large and diverse public demonstrates a sense of concern about environmental problems (Biodiversity Project, 1998). However, people also often do not recognize the implications of the biodiversity loss in exacerbating many problems more familiar and more important to them, such as health and economics. Thus museums and like institutions devoted to the study of nature are still challenged with the goal defined for the biodiversity agenda more than 20 years ago. They must provide enhanced understanding of biodiversity and its degradation that empowers people to make choices based on sound science and reliable recommendations.

To this end, the momentum in both museum research and education in relation to biodiversity is encouraging. Museums and their kinship institutions support their expeditions, collections, research, exhibitions, and educational programs because they are enlisted in a human quest of paramount importance – to understand biodiversity, the evolution of life, and the critical roles of species in ecosystems, and to share this information with a broad public in ways that elicit enlightenment and engagement with issues important for sustaining the quality of life. The degree to which such institutions are successful in this quest in the coming years will be pivotal in determining how effectively societies will deal with the greatest environmental crisis in the history of the human species.

Glossary

Conditions Physical features of the environment, such as substrate type, ambient temperature, or salinity, that affect the ability of organisms to survive, grow, and reproduce.

Dispersal The movement of an individual organism away from its place of origin to the place where it breeds (also, movement by an adult from one breeding location to another).

Pseudoextinction The disappearance of a species from the fossil record due not to the death of all its members but to an evolutionary change that results in it being classified as a new species.

Quaternary The past 2 million years (approximately) of Earth history, including the Pleistocene and Holocene (or Recent) epochs, and characterized by the extreme fluctuations in global temperature that produce the ice ages.

Resources Physical and biotic features of the environment, such as shelter sites or foods, that are required by organisms and are consumed such that use by one individual reduces their availability to others.

Secondary extinction Extinction of a species resulting from the extinction of another species on which it relies.

Introduction

Most species have durations that are very short relative to the history of life, and it is likely that 99% of all species that have ever lived are now extinct. Extinction, therefore, is very much a natural process that produces continuous turnover in the membership of biological assemblages as species are steadily lost by extinction and replaced by speciation. Natural extinctions may be divided into two kinds: those that happened during geologically brief periods of crisis when many taxa disappeared (the mass extinction events) and those during the long intervals of “background” time between mass extinctions. Mass extinctions have attracted a great deal of interest because they bit so deeply into standing biodiversity and because the biotas that reformed after mass extinctions were often quite different from those that existed before; they dramatically reshaped world patterns of biodiversity. However, 95% or more of the total number of extinctions have taken place outside mass extinctions (May *et al.*, 1995). These background extinctions have been most important in producing turnover in species assemblages.

Differences in the probability of extinction for different types of organisms interact with rates of origination of new lineages to shape patterns of biodiversity. To understand patterns of biodiversity it is therefore essential that the process of extinction be understood. In particular, we need to know whether extinction rates vary among different types of organisms and to identify the

characteristics of taxa that make them more or less vulnerable to extinction. Extinction can be studied at the level of higher taxa—genera, families, and so on—but this article is concerned primarily with extinctions of species.

Natural Causes of Extinction

The causes of extinction can be divided into two types: changes in the environment and interactions with other species.

Changes in the Environment

Populations of all species fluctuate in abundance. A large part of this variation is due to chance variation in environmental conditions, such as variations in weather or events such as cyclones, which can be regarded as environmental “accidents.” Species vary in their ability to resist accidents, but for any species there will eventually come an environmental event of sufficient magnitude to wipe it out, or an unlucky succession of smaller blows that drive its abundance down to zero, even when there is no trend in average conditions.

Additionally, species may be driven extinct by directional changes in the environment, such as changes in temperature to levels outside their tolerance or the disappearance of

key habitats. Species can respond to such changes in the environment by (i) acquiring adaptations to the changed conditions ("evolving out of trouble"), (ii) shifting their geographic ranges to remain within a set of suitable conditions ("moving out of trouble"), or (iii) going extinct. If the pace of environmental change is fast relative to the rate of evolution, the first of these responses is much less likely than the other two. The fossil record provides many examples of extinctions apparently driven by environmental changes of many different kinds, especially during mass extinctions events. Environmental changes have been much more extreme and rapid during some periods of Earth history than during others, but environmental conditions have never been truly static. Global temperatures have trended downwards for much of the past 50 million years, and at a finer temporal scale variations in the earth's orbit produce fluctuations in climate with periodicities in the range of 10,000 to 400,000 years. These are called Milankovitch cycles, and during the past 2 million years they have produced the succession of ice ages, but they must have forced rapid swings in climate throughout Earth history (Bennett, 1997).

Interactions with Other Species

The population growth rates of species are constrained by the species predators, parasites, and competitors. The abundance of a species will be reduced if its natural enemies become more abundant or evolve greater efficiency, or if its geographic range is invaded by a new enemy to which it has not evolved defenses.

It is generally difficult to reconstruct such interactions in the fossil record, but some patterns may reflect the impact of predators on prey species. For example, the number of species of endobyssate bivalves gradually declined through the Mesozoic. These species were abundant, immobile, and lay partly exposed on the open seafloor. Their decline coincided with radiations of marine crabs, teleost fish, and carnivorous snails, groups that account for most predation on modern bivalves and to which the endobyssates must have been vulnerable (Stanley, 1979). The few present-day survivors of the group live in conditions with low predator pressure. Recent experience shows that prey species can be rapidly driven extinct by unfamiliar predators that invade their habitat. The carnivorous snail *Euglandina rosea*, for example, has caused the extinction of hundreds of species of endemic snails, including 600 of more than 1000 original species from the Hawaiian Islands, since its introduction to many Pacific islands in the 1970s. Such a rapid course of events would be unresolvable in the fossil record.

Probably, the impacts of environmental changes and of other species interact in subtle ways to cause extinction. For example, a species might experience a slight environmental change that reduces its population without driving it extinct and to which it could readily adapt given sufficient time. However, the same change might favor a competitor or trigger a range expansion by an unfamiliar predator suited to the new conditions. Interactions of this kind could mean that quite small environmental changes could have dramatic consequences leading ultimately to extinction.

Lifetimes of Species

Variation among Taxonomic Groups

The oldest extant species known is the tadpole shrimp, *Triops cancriformis*, a small freshwater crustacean found in temporary pools in arid regions of Eurasia and north Africa that is indistinguishable from 180-million-year-old fossils bearing the same name. Most species do not live to this age, as shown in Table 1.

The lifetime of a species begins with its origin in a speciation event and ends either when it dies out, leaving no descendants, or when its characteristics have been sufficiently changed by evolution that it is classified as a new species. The first type of disappearance of species is "real" extinction, and the second is referred to as pseudoextinction. This distinction is important but not easy to draw in practice. Our understanding of species life spans derives from study of the fossil record, and when a recognizable species disappears from the record it can be difficult to determine whether it has died out or evolved into something else. Information in Table 1 is based on real extinctions when the distinction can be made,

Table 1 Durations of species and extinction rates for major groups of organisms in the fossil record

<i>Taxon</i>	<i>Estimated mean species duration (millions of years)</i>	<i>Extinction rate (extinctions per million species years)</i>
Single-celled organisms		
Diatoms	8	0.12
Dinoflagellates	13	0.08
Planktonic foraminifera	7–20	0.14–0.05
Benthic foraminifera	25	0.04
Plants		
Early vascular plants	10–14	0.1–0.07
Pteridophytes	7–15	0.14–0.07
Gymnosperms	2–15	0.5–0.07
Monocots	4	0.25
Dicots	3	0.33
All invertebrates	11	0.09
Reef corals	20	0.05
Mollusks:		
Marine gastropods	10	0.1
Marine bivalves	15	0.07
Mesozoic ammonites	1	1
Upper Cambrian trilobites	1.3	0.77
Marine ostracods	8	0.12
Silurian graptolites	2	0.5
Echinoderms		
Echinoids	6	0.17
Crinoids	6.7	0.15
Bryozoans	12	0.08
Freshwater fish	3	0.33
Birds	2.5	0.42
Mammals	1.4	0.71
Cenozoic mammals	1–2	1–0.5
Horses	4	0.25
Primates	1	1

but most estimates include an unknown combination of real and pseudoextinctions.

There is considerable variation in species life spans among different groups of organisms. In general, it seems that species of unicellular organisms last longer than species of multicellular organisms, and invertebrates appear to last longer than vertebrates. The most long-lived animal groups tend to be marine rather than terrestrial, although too little is known about species durations of marine vertebrates or terrestrial invertebrates to judge differences between marine and terrestrial species independent of the difference between vertebrates and invertebrates. Some marine invertebrate groups that are now entirely extinct (the trilobites, ammonites, and graptolites) had short species durations, even though they were successful, abundant, and species rich for long periods of geological time. Among plants, species durations were longer in groups that appeared early in the evolutionary history of plants but have tended to shorten in recently evolved groups.

The inverse of the typical duration of species in a given taxonomic group can be used as a measure of the probability of extinction per unit time for species belonging to that group: Long durations equate to low probabilities of extinction. In **Table 1**, probabilities of extinction have been expressed as the rates of extinction per million species years. Thus, marine gastropods typically last 10 million years, so a sample of 1 million marine gastropod species would be expected to experience 0.1 extinctions per year.

Variation within Taxonomic Groups

The distributions of species lifetimes within higher taxa are typically right-skewed: Most species have short durations, but a small minority are long-lasting (**Figure 1**). There could be two causes for this pattern. First, only a few species might have characteristics that make them intrinsically resistant to extinction, whereas most are sensitive to extinction risk. Second, species might not vary in their susceptibility to extinction, but

if many independent factors can cause extinction only a small minority of species will be lucky enough to avoid extinction for long. Probably both factors play a part in shaping distributions of species durations.

Risk of Extinction in Relation to Species Age

Does the likelihood that a species will go extinct depend on its age? One might think that it should because the longer a species stays in existence the more adaptations to its environment it can accumulate; older species should therefore be better at avoiding extinction. This idea can be tested by examining species survivorship curves. A species survivorship curve shows the relationship between age and the proportion of species in a taxon surviving to each age. Such curves are typically log linear; that is, when the proportion surviving is plotted logarithmically its decline with age approximates a straight line. This shows that the proportion of species going extinct is approximately constant with respect to age.

The constancy of extinction probability with species age can be explained by assuming that the environment of any species is continually changing so that even if the species continually adapts, its fitness lags behind the current condition of the environment. Thus, no matter how long a species lasts it can never reach a condition of optimal adaptation. There are two forms of this explanation. The first assumes that the probability of extinction for a species is determined primarily by its interactions with other species and that each species is under constant selection pressure to increase its fitness relative to these other species. However, adaptations in one species that increase abundance at the expense of other species will be met by counteradaptations from them so that, on average, no species improves its fitness with time. This is the Red Queen hypothesis, named after the character in Lewis Carroll's *Alice Through the Looking Glass* in whose world "it takes all the running you can do, just to stay in one place." The Red Queen hypothesis predicts that extinction rates will be

Figure 1 Species durations of Silurian graptolites of the British Isles. (Reproduced from Stanley SM (1979) *Macroevolution: Patterns and Process*. San Francisco: Freeman, with permission from W.H. Freeman and Company.)

approximately constant with respect to absolute time. The second form of the explanation assumes that it is the abiotic environment that is continually changing. Changes in the abiotic environment will tend to be episodic and will therefore produce fluctuations in extinction rates with time, but their effects will still be independent of species age. It is not clear which form of the hypothesis is closer to the truth.

The Selectivity of Extinction

Extinction may be largely a matter of the bad luck of environmental change, exacerbated perhaps by pressure from other species; however, the fact that species durations vary so widely among higher taxa suggests that biological characteristics of species influence their susceptibility to extinction. Three types of studies have helped to identify these characteristics.

First, the attributes of species that have short versus long durations in the fossil record can be compared. A common variant of this technique compares species that persisted through mass extinction events with those that did not. Second, the living faunas of “land-bridge islands” can be compared with their presumed original faunas. A land-bridge island is an island formed as a result of isolation from the mainland by rising sea levels during the Pleistocene. Such islands typically have fewer species than do similar areas of mainland habitat to which they were once connected, reflecting extinctions caused by the pressure of reduced habitat area. Third, extinction of local populations can be observed directly in contemporary ecological studies. The second and third approaches focus on population rather than species extinctions, but the extinction of a species is the end point of a series of population extinctions, so such studies may still reveal traits that correlate with risk of extinction at the species level.

The following traits consistently emerge from many studies of the selectivity of extinction: rarity, dispersal ability, body size, and specialization.

Rarity

The commonness or rarity of a species is a function of two factors: its geographic range and its population density where it occurs. Both components of rarity influence extinction risk.

Geographic Range

There is strong evidence from the fossil record (mainly for marine invertebrates) that species with large ranges have lower extinction rates (Jablonski, 1995; McKinney, 1997). There are probably two causes for this effect. First, at a given scale, a disturbance will affect a smaller proportion of the range of a widespread rather than of a geographically restricted species. In the extreme, a single catastrophic event may wipe out a localized species but have little impact on a widespread species. Second, even if an environmental change affects a very large area, it is likely that some populations of widespread species will persist in isolated refuges that provide some local protection from the change. Species that hang on in such refuges may reinvade their original ranges once conditions

improve. This is probably part of the explanation for the existence in the fossil record of “Lazarus species” that vanish during periods of environmental crisis and then reappear much later. The effect of range size on extinction risk tends to be strongest for background extinctions, and it may weaken or disappear in mass extinctions. This seems to have been the case for marine mollusks, for example (Jablonski, 1991), and is probably because mass extinctions were caused by events that affected such large areas and had such profound impacts that even widespread species were susceptible to them.

Local Abundance

Population density is generally not well represented in the fossil record, but patterns of extinction of populations on land-bridge islands and in the present day show that local extinction is more likely for species with low population densities. For example, Foufopoulos and Ives (1999) found that reptile species with low population densities were more likely to go extinct from land-bridge islands in the Mediterranean Sea. The causes of extinction of small populations have been widely discussed in the literature on conservation. Briefly, small populations are more vulnerable than large populations because (i) they may go extinct more quickly when chance environmental variation causes fluctuations in abundance; (ii) they are affected by chance demographic fluctuations, such as occasional production of biased sex ratios of offspring, that would be averaged out in large populations; (iii) they may lose genetic variation and experience high levels of inbreeding and inbreeding depression; and (iv) they may be subject to Allee effects—that is, social or reproductive dysfunction as a direct result of low numbers.

The Relationship between Range and Abundance

The components of rarity—geographic range size and population density—are generally positively related among species: Species with small geographic ranges also tend to have low population densities, and wide-ranging species have high population densities. This pattern has been found in many terrestrial plant and animal taxa, although it remains almost unstudied in marine organisms. Why there should be a positive relationship between range and abundance is not clear. Several ecological mechanisms have been proposed as its cause, but two ideas have been especially influential. First, Brown (1995) argued that niche breadth is positively correlated with both range size and population density because species with broad niches can exist under a wider range of conditions and use more types of resources than can species with narrow niches; variation among species in niche breadth therefore produces a positive relationship between range and density. Second, species that reach high local densities should be both more resistant to extinction on habitat patches because their populations are larger and produce more migrants that are able to recolonize habitat patches after local extinctions (Hanski, 1999). High local abundance therefore results in wide geographic distribution.

To the extent that geographic range and local abundance affect extinction risk independently of one another, the correlation between them should exaggerate differences among species in extinction risk. Rare species face double jeopardy:

Figure 2 Relationships between size of geographic range and population density for species of Australian marsupials: (a) all species other than those defined as ancient and (b) ancient species only. Ancient species are those that diverged from their closest living relative more than 4 million years ago and have therefore demonstrated resistance to extinction. The shaded triangle defines the region of distribution-abundance space from which species would need to have gone extinct to produce the pattern observed among ancient species. (Reproduced with permission from Johnson CN (1998) Species extinction and the relationship between distribution and abundance. *Nature* 394: 272–274.)

The vulnerability that comes from having a small range is compounded with the vulnerability due to low abundance. Common species, on the other hand, are likely to be highly resistant to extinction because they combine high abundance with large ranges. For example, Johnson (1998) showed that among Australian marsupials, ancient species (those that diverged from their closest relative more than 4 million years ago) are very unlikely to have both small ranges and low population densities, although this combination occurs frequently among young species (Figure 2). This suggests that species with low abundance and small ranges tend to be short lived. There are ancient marsupials with small ranges but they have unusually high densities, and conversely there are species with low densities but they have unusually large ranges, implying that a high density can compensate for the vulnerability that comes from having a small range and vice versa.

Spatial Structure of Populations

Another aspect of rarity is ubiquity or patchiness of distribution within the geographic range. The distributions of practically all species are discontinuous at some scale, but the degree of patchiness varies, reflecting specialization for habitats or resources that are themselves patchily distributed. In a species that has a patchy distribution, metapopulation dynamics are likely (Hanski, 1999). That is, the risk of extinction of populations on discrete patches of habitat may be high, but local populations are eventually reestablished by migrants from other populations. Recolonization will involve a time lag that depends on the distance between patches and the dispersal ability of the species.

A general deterioration in the quality of habitat for a species is likely to cause contraction of larger habitat patches and the disappearance of smaller ones, causing local extinctions and simultaneously increasing the distance between surviving patches and thus reducing the probability of migration. Patchily distributed species should therefore be more likely to go extinct as a result of environmental change than should continuously distributed species. The sensitivity of patchy species to environmental change has been demonstrated for insects in Great Britain subject to human-caused changes (Webb and Thomas, 1994), but it is likely to be general to any form of shift in environmental conditions. Patchiness of distribution is loosely correlated with the other components of rarity so that widespread and locally abundant species tend to be continuously distributed within their ranges, whereas rare species are likely to be patchy.

Dispersal Ability

Dispersal ability is positively associated with species longevity for two reasons. First, species that disperse widely tend to have large geographic ranges, and their resistance to extinction can be a direct result of large range. Marine gastropod snails, for example, have two different forms of development. In some, the egg is released into surface waters and develops into a larval form that feeds in the plankton and drifts widely before settling and developing into an adult snail. This form of development promotes wide dispersal. Others have direct development in which eggs and young grow up close to the parent. Species with planktonic development have larger geographic ranges and longer durations in the fossil record than do species with direct development (Jablonski, 1995).

Second, species that disperse widely are better able to recolonize after going extinct from part of the range, and they can more rapidly shift their ranges to track changes in the distribution of their preferred climates and habitats. During the Quaternary in the Northern Hemisphere, the distribution of habitats changed very rapidly as ice sheets repeatedly advanced and receded. These changes produced remarkably few extinctions among Northern Hemisphere beetles. Instead, species shifted their geographic ranges to keep pace with the changing distribution of habitats, an effect that was more dramatic in flighted than in flightless species (Coope, 1995). Probably, dispersal ability and local abundance interact to confer high resistance to extinction because high local abundance means that large numbers of dispersers are produced,

resulting in the potential for rapid shifting of range boundaries as conditions change. This combination of characteristics might protect species that have specialized habitat requirements and small geographic ranges and would otherwise be vulnerable to extinction.

Body Size

It often seems to be the case that large-bodied species are at higher risk of extinction than small-bodied species. Although there are exceptions, this pattern is reasonably consistent in the fossil record both for background extinctions and for mass extinctions (McKinney, 1997), and it also emerges in extinctions on land-bridge islands (Brown, 1995). There are several reasons why large-bodied species might be particularly vulnerable to extinction:

1. Potential rate of population increase declines with body size because large-bodied species generally have longer generation times and lower fecundity than do small-bodied species. This means that large-bodied species will generally recover more slowly from population declines, and because they produce fewer offspring they may be slower to track habitats than will small-bodied species.
2. Individuals of large-bodied species generally need larger areas, and large-bodied species are therefore strongly affected by declines in habitat area.
3. Population density tends to decline with body size so that large species are often naturally rare. This is partly compensated by a tendency for size of geographic range to increase with body size, but this relationship is often weak or absent so that total population size is usually much less for large than small species. The decline in population density with body size is clearest when species of very different size (e.g., mice and elephants) are compared, but in guilds of ecologically similar species it is often the case that density increases with body size, possibly because larger species are better competitors for resources (Cotgreave, 1993). At this finer scale of comparison, therefore, large-bodied species might be more resistant to extinction than small-bodied species.

Specialization

Species can be classed as “specialists” or “generalists” on three criteria: the range of conditions that they are adapted to tolerate, the range of resources that they are able to use, and the degree of their evolved dependence on a small number of other species.

Conditions

Species that are narrowly adapted to environmental conditions are likely to be the first to go extinct when the environment changes. This is difficult to demonstrate in the fossil record, however, because it is not possible to measure directly the environmental tolerances of fossil species. Instead, environmental tolerances are inferred from geographic distributions. Species with small geographic ranges will necessarily occupy a narrow range of climate zones and habitats, but it

does not follow from this that their environmental tolerances are narrow. Some species that could potentially be widely distributed have small ranges because of population history, geographic barriers to movement, or poor dispersal ability or because range expansion is prevented by interactions with other species (competitors, predators, and so on). Therefore, although there is abundant evidence from the fossil record that species with small geographic ranges are extinction-prone, there is much less evidence for the commonsense view that the breadth of tolerance of environmental conditions directly affects extinction risk.

Resources

Species that depend on a narrow range of types of resources are likely to be more sensitive to changes in resource abundance than generalists that can easily switch resources. This vulnerability may be partly compensated by the fact that specialization on a particular resource may be more likely to evolve if that resource is abundant and widespread. For example, feeding on grasses by mammals requires extensive specialization of the teeth and digestive system, and increases in body size, to overcome the abrasiveness and poor nutritional quality of grasses. However, because of the abundance of grasses many mammals have evolved these adaptations, and grazing mammals typically have high local abundance and large geographic ranges. Nonetheless, grazing mammals in Africa have suffered higher extinction rates since the Miocene than mixed grazer/browsers, as the extent of grasslands has fluctuated during the Pliocene and Pleistocene (Vrba, 1987).

Interactions

Specialization is taken a step further in species that have evolved a close dependence on one or a small number of other species. For example, many herbivorous insects feed on only one species of plant, and many predators attack only one or a small number among many possible species of prey. Of particular interest are mutualistic interactions, in which species provide benefits to one another. Figs, for example, rely on fig wasps for pollination, and fig wasps in turn lay their eggs only in the flowers of figs. This interaction tends to be highly species specific, with each species of fig visited by only one species of fig wasp and each partner in the interaction completely dependent on the other for reproduction. Such tight species specificity results from coevolution, in which each species in the interaction evolves special characteristics in response to evolutionary changes in the other to increase its benefit from the interaction.

Specialization of this kind is classically regarded as an extinction trap because the specialist will inevitably go extinct if the species that it depends on goes extinct or becomes very rare. This view is probably an oversimplification. Careful study of some species-specific interactions has revealed more flexibility and greater potential for rapid evolutionary response to changes in the abundance of interacting species, including the ability to switch to new partners, than was previously assumed (Thompson, 1994). Also, mutualistic interactions have the general effect of increasing the geographic range and abundance, and stabilizing the population dynamics, of both partners in the interaction. These ecological benefits may at

least partly compensate for the vulnerability caused by dependence on another species.

Because interactions between species are not revealed in detail in the fossil record, there is little direct information on rates of secondary extinction. It is sometimes possible, however, to evaluate the risks of secondary extinction from study of living communities. Many plants cannot set seed without cross-pollination and rely on animals to transfer pollen. Such plants should be vulnerable to reproductive failure, and possibly extinction, if their pollinators decline, and species that have only one or a small number of pollinators are likely to be especially vulnerable. This vulnerability can be reduced by traits such as the ability to propagate vegetatively that reduce demographic dependence on seeds. Bond (1995) showed that in some plant communities there are no species that have both a high dependence on animal pollinators for seed set and a high demographic dependence on seeds, despite wide variation among species in both sets of characteristics (Figure 3). One explanation for this pattern is that such species are unusual because their high dependence on other species means that they are very likely to go extinct.

Reproductive and Life History Traits

A wide variety of reproductive and life history traits may influence the likelihood of extinction in some circumstances. Perhaps the most important is sexual reproduction. Sexual lineages appear able to evolve more quickly than parthenogenetic ones because genetic recombination generates more variability among

Figure 3 The relationship between an index of dependence on animal pollinators for seed set and dependence on seeds for regeneration for species of spring flowering herbs in a temperate deciduous forest. Any species that was both dependent on pollinators for seed set and dependent on seeds to regenerate would be considered at high risk of extinction due to pollinator failure. (Redrawn with permission from Bond WJ (1995) Assessing the risk of extinction due to pollinator and disperser failure. In: Lawton JH and May RM (eds.) *Extinction Rates*, pp. 131–147. Oxford: Oxford Univ. Press.)

individuals on which natural selection can act. Sexual species may therefore be better able to adapt to changed environmental conditions or to meet new challenges from other species. The taxonomic distribution of parthenogenetic lineages suggests that they are short lived: With few exceptions, no higher taxa (genera, families, etc.) consists solely of parthenogens; almost all parthenogens have close sexual relatives and are likely to be recently derived from sexual species (Maynard Smith, 1978).

Species with resting or resistant stages in their life cycle may be better able to pass through environmental catastrophes than species in which all life stages are vulnerable to environmental changes. In the islands of the Lesser Antilles, for example, butterflies are better able to persist on small islands than are birds or mammals, perhaps because they are able to pass through unfavorable seasons as diapausing eggs and pupae. Similarly, reptiles and amphibians are resistant to extinction, possibly by virtue of their ability to survive for long periods in protected micro environments without having to feed (Ricklefs and Lovette, 1999).

Geographic Patterns in Extinction

Natural extinction rates vary along two major geographic axes: Extinction rates are lower for marine than terrestrial organisms, and extinction rates may be higher near the equator than at high latitudes. The low extinction rates of marine organisms are presumably due to their large geographic ranges—the oceans are bigger and less subdivided than the continents—and the high dispersal ability of many species that have larval life stages that drift in the plankton. The effects of latitude on extinction rates are less distinct, but where extinction rates have been shown to vary with latitude they tend to be higher in the tropics. Tropical species often have smaller geographic ranges and lower population densities than species at higher latitudes and may thus be more vulnerable to the effects of environmental change (Lawton, 1995). Also, some particularly species-rich tropical environments, such as the low-sediment, low-nutrient, shallow-water platforms that support reef and related communities, are easily disrupted by changes in climate and sea level (Jablonski, 1995).

Natural Extinction and Trends in Biodiversity

The diversity of any lineage of organisms through time reflects the balance of the rates of loss of species by extinction and gains by speciation. Because extinction rates vary among lineages, extinction is an important factor shaping patterns of biodiversity. Much of the explanation for the very high diversity of insects is that, owing presumably to traits such as small size, high abundance, and high mobility, they have low extinction rates. Essentially no insect families have gone extinct during the past 50 million years, and some living genera and species with good fossil records are of Miocene age or older (Labandeira and Sepkoski, 1993). Species diversity of insects has therefore accumulated over long periods of time. Mammals, on the other hand, appear to evolve and speciate rapidly, but they are a minority taxon because their extinction rates are high.

Insects and mammals provide an extreme example of contrasts in the balance of extinction and speciation rates, but in general extinction and speciation rates are positively correlated among different lineages (Figure 4). Such a relationship could arise if total species number in a lineage is held at equilibrium by competition between species so that a new species can only establish by occupying a niche left vacant by a species that has gone extinct. However, the relationship was first shown for groups of animals undergoing rapid increase in diversity (Stanley, 1979). There are three possible causes of the correlation between rates of speciation and extinction:

1. The effects of dispersal and gene flow: Dispersal rates should be correlated with resistance to extinction, but the gene flow resulting from high dispersal should also prevent genetic divergence of populations, thus impeding allopatric speciation. This explanation may apply to marine gastropods during the Late Cretaceous, when lineages with planktonic larvae and large ranges not only were less likely to go extinct but also were less likely to produce new species than those with direct development and restricted dispersal (Hansen, 1983).
2. The effects of niche breadth: Ecologically specialized species are likely to be vulnerable to environmental change, but they also tend to have patchy distributions, and this spatial subdivision should promote divergent evolution of local populations and the generation of many species. Generalists may be resistant to extinction, but their lack of spatial population structure also impedes divergent evolution among local populations.

Figure 4 The relationship between extinction rate and diversification rate for lineages of animals (○) and plants (●). Because diversification rate equals speciation rate minus extinction rate, the positive relationship shows that rates of extinction and speciation must be positively correlated (if not, the relationship on the graph would be negative). Extinction rates are measured per million species years and calculated as the reciprocal of species durations.

3. The effects of rarity: Species with small populations are prone to extinction. Somewhat controversially, it is believed that speciation may be enhanced by small or fluctuating population sizes (Futuyma, 1998).

Because extinction is selective for particular characteristics of species, it can act as a filter through which certain types of species are more likely to pass. Selective extinction therefore shapes the composition of ecological assemblages of species. This filtering effect can be seen most clearly in mass extinctions, which typically leave in their wake “survival faunas” dominated by small numbers of wide-ranging and abundant generalist species of a few simple ecological types. The examples shown in Figures 2 and 3 illustrate some more subtle effects of the continuous operation of extinction filters, shaping respectively the patterns of distribution and abundance in living marsupials and the combinations of demographic characteristics of living plants.

In some cases, directional trends in evolution and the development of communities can be opposed or curtailed by selective extinction. This effect can produce taxon cycles, which occur if derived species tend to evolve characteristics that make them vulnerable to extinction. For example, species that colonize islands are often generalists that are abundant and competitively dominant and quickly become widespread. Their descendants, however, tend to become more specialized and less mobile, occupy fewer habitats, lose their competitive ability, and sustain smaller and more subdivided populations. These trends eventually lead to extinction and the repetition of the cycle as sets of derived species are replaced by newly invading generalists (Ricklefs and Miller, 1999). Taxon cycles are most visible on island chains, where ecological communities are relatively simple and the patterns of distribution of related species on different islands provide clues to the direction of evolution. However, similar processes probably operate over larger areas on continents and in the oceans.

What can the study of natural extinctions teach us about the coming wave of human-caused extinctions? There are at least two messages. First, species durations among different taxa in the fossil record are positively related to rates of endangerment of living species in the same taxa (McKinney, 1997). This suggests that the characteristics that have made species vulnerable to extinction under natural conditions also make them sensitive to human impacts on the environment, and in the absence of better information these characteristics could be used to identify species likely to be at risk in the near future. Second, the selectivity of extinction means that extinction rates will be higher in certain ecological types and taxonomic groups than in others, and if environmental pressures continue for a sufficient amount of time some groups may be removed entirely. The result will be a much greater impoverishment of biodiversity than would be the case if extinctions were randomly distributed among species.

Threatened Species: Classification Systems and Their Applications

Rebecca M Miller, IUCN Red List Unit, Cambridge, UK

© 2013 Elsevier Inc. All rights reserved.

Glossary

Biodiversity (from biological diversity) The variety of all life on Earth. Includes genetic diversity (diversity within species), organismal diversity (diversity between species), and the diversity of ecosystems and ecological processes.

Ecosystem services Benefits that humans derive from the resources and processes supplied by natural ecosystems (e.g., water quality, climate regulation; pollination; food, fuel, and raw materials; nutrient cycling).

Endangered Often interpreted generically to mean having a relatively high risk of extinction (*see* Threatened). In many systems that classify extinction risk, a specific category that indicates a particular degree of extinction risk (e.g., in the IUCN Red List Categories and Criteria, Endangered falls between Vulnerable and Critically Endangered; on the US Endangered Species List, Endangered is the highest category of risk, followed by Threatened).

Endemic species Species found only within a specific geographic area on Earth (e.g., a habitat type or region) and nowhere else.

Extinction risk The likelihood that a taxon will disappear or die out within a given area (e.g., one country or the entire world) and over a definable time period.

Taxon (plural taxa) Taxonomic group or entity at any level such as a genus, species, subspecies, or population.

Threatened Facing a relatively high risk of extinction in a definable time period. May apply to any taxonomic (e.g., genus, species, subspecies, variety) or geographic (e.g., population, subpopulation) rank. Often used interchangeably with endangered (though *see* the definition of endangered). In some systems that classify extinction risk, "Threatened" is a category indicating a specific level of extinction risk.

Threatened species list (also often called a red list or red data book) Publication defining the extinction risk of assessed taxa within a given region. In its most minimal form, just a list of names and categories of threat, but frequently also includes additional supporting information about the biology, ecology, threats, and conservation of the taxa assessed.

Introduction

There is no doubt that the world is facing a biodiversity crisis of epic proportions. The rate of species loss is greater now than at any time in human history, with extinctions occurring at rates hundreds of times higher than historical extinction rates. The question at the forefront of the conservation debate today is, What can we do about it?

To answer this fundamental question requires information about the current status and trends of biodiversity. We need to know what is being lost, where it is disappearing most quickly, what is causing the declines, and, perhaps most important, what measures must be taken to protect and restore species and their habitats. As evidence accumulates that the loss of biodiversity will have major consequences for ecosystem functions and services, and therefore for human health and well-being (*Millennium Ecosystem Assessment, 2005*), the arguments for finding solutions to these questions become even more compelling.

Inventories or lists that aim to quantify species extinction risk can provide insight into many of these pressing issues. The principle aim of a threatened species assessment is to estimate a species' risk of extinction in a comparable, repeatable, transparent, and objective manner. Threatened species lists, in turn, have multiple conservation applications. They permit us to quantify the magnitude of the contemporary extinction crisis so as to monitor the status of biodiversity and measure current trends; they draw attention to the plight of threatened species and help mobilize political and public support for conservation measures; and they help guide conservation

efforts, allowing us to optimize investment of the limited conservation resources available by taking action where it is most needed.

These lists have strong scientific, political, and public relevance. While conservationists debate how many species are threatened, where they are found, how quickly they are moving toward extinction, and what to do to protect them, decision makers are looking for guidance on how best to set priorities to protect species, and the public seeks information about why other living creatures are disappearing, what our role is in the process, and what they as individuals can do to help.

In truth, extinction encompasses more than just species loss: global species extinction results from the progressive loss of individuals and populations, causing a decline in genetic diversity and ultimately leading to reduced ecosystem function as key species drop out of the system. Biodiversity loss could be measured on any number of alternative scales such as biomes, habitats, populations, or genes. But many consider species the fundamental unit of biodiversity (*Wilson, 1992*), and species are the most common and easily measured unit for assessing the state of biodiversity; moreover, threatened species are among the most visible and easily understood symbols of the rising tide of extinctions (*Wilcove, 2010*), making them an emotive and politically powerful measurement of biodiversity loss.

This chapter explores the history and current status of threatened species assessment, including a brief outline of extinction vulnerability, a summary of the various methods employed to assess the threat status of species, and a more

detailed look at what these assessments can tell us about the status of biodiversity today and how they are used in conservation planning. It does not attempt to be comprehensive, as many of these concepts are explored in more detail in other chapters, but rather places the concept of threatened species assessment in context within the wider world of conservation planning, prioritization, and action.

History of Threatened Species Lists

The first calls of alarm at rapid species loss were raised more than a century ago. By the early 1900s, several works had been published highlighting recent extinctions in British animals (Harting, 1880; Hudson, 1894) and declining and extinct wildlife around the world (e.g., Anon, 1928; Dollman, 1937; Johnson, 1937). In 1913, William Temple Hornaday warned of the imminent extinction of American game species and drew support for legislation and legal reforms to protect wildlife (Hornaday, 1913). The path toward using threatened species lists to advocate legislative protection measures had been opened.

In the 1940s and 1950s, threatened species publications expanded to include information on the factors contributing to the depletion of the world's mammalian and avian faunas (e.g., Allen, 1942; Harper, 1945; Greenway, 1958). Following this lead, the International Union for Conservation of Nature (IUCN) spearheaded the concept of Red Data Books (RDB) as a "register of threatened wildlife that includes definitions of degrees of threat" (Fitter and Fitter, 1987). These publications were used widely in scientific, political, and popular contexts to highlight the world's most threatened species (Mace *et al.*, 2008), cementing IUCN's role as a leader in global threatened species assessment.

Early Red List assessments, lacking any standardized criteria, relied on the experience and opinion of experts. Until the late 1960s, a variety of qualitative terms and categories were used to define different levels of extinction risk. Rather than focusing solely on probability of extinction, these initial threat categories were a mixture of several issues, including likelihood of extinction, causes of threat, severity of threat, the nature of population vulnerability, and priority for conservation action. In addition, they depended on subjective interpretations rather than objective criteria and were thus open to biases of individual preference or political influence (Mace *et al.*, 2008).

Seeking a more rigorous, objective, and repeatable system, and in view of the increasing incorporation of threatened species lists and categories into international, national, and local legislation that mandated or prohibited certain actions, IUCN initiated a review of the Red List categories in 1984 (Fitter and Fitter, 1987; Mace *et al.*, 2008). An extensive period of development, consultation and testing across a wide range of taxonomic groups resulted in a revised risk-ranking system of data-driven quantitative criteria (Mace and Lande, 1991; IUCN, 1994), with which several threatened species lists were produced (Baillie and Groombridge, 1996; Oldfield *et al.*, 1998). The categories and criteria were subsequently finalized in 2001 (IUCN, 2001).

Many other systems for assessing extinction risk were developed from or in parallel to the IUCN system. At least 25 categorization systems are used across the North American continent alone (de Grammont and Cuarón, 2006), giving an indication of the total number of different categorization systems that must exist worldwide. Many of these systems suffered the same dilemma as the early IUCN system in mixing the concept of extinction risk with priority for conservation (see Box 1); although this has been remedied in some systems, many others still conflate the two.

Inspired by the IUCN RDB and the expanding global awareness of species declines, national RDB began to appear in the late 1960s. The US federal government produced a publication on rare and endangered wildlife in 1966; the first RDB for the former USSR was published in 1978 (Scott *et al.*, 1987). In 1968, the Brazilian government published its first Official List of Threatened Plant and Animal Species, using the IUCN categories in place at the time. There has since been a virtual explosion of national lists of threatened and endangered species; 3562 current and historical threatened species lists have been reported for the European nations alone (Köppel *et al.*, 2003). These lists have become important tools for conservation and today play a major role in informing and influencing national legislation, international conventions, conservation planning and resource allocation, and scientific research.

Vulnerability to Extinction

The assemblage of species that exist at any one time in history is a function of two processes: extinction of existing species and the evolution of new species. Indeed, of all the species that have ever lived, only 2% to 4% are alive today (May *et al.*, 1995). However, conservative estimates indicate that the current rate of extinction is 100–1000 times higher than historical rates (Baillie *et al.*, 2004). Other estimates suggest that current extinction rates may be 1000–10,000 times higher than historical rates of extinction (Pimm *et al.*, 1995; Baillie *et al.*, 2004). We are thus now approaching what many scientists believe to be the sixth great extinction event (Wilson, 1992; Myers, 1993; Barnosky *et al.*, 2011), which could ultimately result in the loss of a large proportion of the biodiversity on the planet today. Although the ultimate fate of all species is extinction, by definition threatened species face a relatively higher risk of extinction in the near future than nonthreatened species. What then makes a species vulnerable to extinction?

Extinction risk is a function of intrinsic characteristics and extrinsic factors and the complex manner in which these various biological traits and threatening processes interact (Mace *et al.*, 2008). Intrinsic traits demonstrated to be associated with a high risk of extinction include high trophic level, low population density, slow life history or low fecundity, high habitat specificity, and small geographical range size (Bennett and Owens, 1997; Purvis *et al.*, 2000). Species with these traits are more sensitive to environmental instability and are less able to adapt to or recover from environmental or ecological changes.

Population size and the ability of a population to recover from natural or anthropogenically induced declines are

Box 1**Assessing extinction risk versus setting conservation priorities**

Extinction risk is an important factor to consider when deciding whether or not to devote scarce attention and resources to the conservation of a particular species, but it is certainly not the only one (**Box 1 Figure**). Indeed, a high risk of extinction does not imply a high priority for action. The ultimate success of conservation efforts often depends more on societal and economic factors than biological ones, and when it comes to deciding how best to allocate the scarce resources available, difficult decisions must be made. Fundamental questions that must be answered include but are not limited to: What needs to be done to conserve the species? Do we have the required knowledge and expertise? Are sufficient funds available? What are the prospects for successful intervention? What economic and cultural importance does the species have? Is it taxonomically, genetically, or ecologically unique? What are the conditions within the region? What is its global status? What proportion of the global population is found within the region? Although extinction risk assessment should be as objective as possible, ultimately the setting of conservation priorities involves value judgments and is therefore part of a broader sociocultural and political debate. Even when incorporating subjective values into a flexible and adaptable weighting system, however, effective priority-setting mechanisms should always be explicit and transparent.

Box 1 Figure Factors to consider when establishing conservation priorities (the factors shown are illustrative, not exhaustive). The variables considered will depend on the purpose of the priority-setting exercise and conditions within the region. Different factors may be summed, multiplied, or otherwise weighted to achieve an ultimate ranking of conservation priorities. Reprinted from Miller RM, Rodríguez JP, Aniskowicz-Fowler T, *et al.* (2007) National threatened species listing based on IUCN criteria and regional guidelines: Current status and future perspectives. *Conservation Biology* 21: 684–696.

Despite this reality, national threatened species lists often move beyond assessing extinction risk to incorporate conservation priority setting or degree of protection afforded to the species into the listing criteria. Even when the assessments reflect extinction risk only, many countries interpret these lists as a direct priority for conservation action by incorporating the assessments directly into national legislation. Some countries have resolved this issue by producing at minimum two separate lists: (1) a scientific list of nationally threatened species that is produced using objective and explicit criteria designed purely to assess risk of extinction and (2) a list of species that are priorities for receiving conservation funding and attention, which is often produced using a weighting system and incorporating a number of factors in addition to threat status. Numerous other methods that consider extinction risk alongside other factors have been proposed for prioritizing species for conservation action (e.g., Avery *et al.*, 1995; Dunn *et al.*, 1999; Bollmann *et al.*, 2002; Rodríguez *et al.*, 2004; de Grammont and Cuarón, 2006; Miller *et al.*, 2006). It is important to make this clear distinction to prevent blurring the line between extinction risk assessment, which is a scientific endeavor, and conservation priority setting, which is very much a value-based judgment.

References: Mace and Lande, 1991; Avery *et al.*, 1995; Collar, 1996; Dunn *et al.*, 1999; Gärdenfors, 2001; Gärdenfors *et al.*, 2001; IUCN, 2001; Bollmann *et al.*, 2002; Rodríguez *et al.*, 2004; de Grammont and Cuarón, 2006; Miller *et al.*, 2006; Mace *et al.*, 2007; Miller *et al.*, 2007; Hoffmann *et al.*, 2008; Brito *et al.*, 2010.

particularly important in determining extinction risk (Purvis *et al.*, 2000). “Rare” species, those with small populations or geographic ranges (or both), are far more likely to go extinct than widespread or higher-density species, as are species with

fluctuating populations and those suffering rapid declines (Pimm and Jenkins, 2010). However, rarity does not in itself cause extinction. It is when those small populations are confronted with novel or altered environmental conditions or

threatening processes and find it difficult to adapt that they begin to slide toward extinction.

The manner in which different threat processes interact with different biological traits has a significant impact on extinction risk. For example, persecution and introduced predators have been correlated with an increase in extinction risk in birds with large body size and long generation times, whereas habitat loss has been correlated with an increase in extinction risk in small-bodied birds that have specialized habitat requirements (Owens and Bennett, 2000). Carnivores within reserves are more likely to go extinct if they have large home ranges (Woodroffe and Ginsberg, 1998).

Extinction risk can have as much or more to do with the driving threat factors as with intrinsic biological traits. Regardless of the size of a species' population, how quickly it breeds, or the extent of its current range, if the pressures put on it are too great and remedial measures are not put in place quickly enough, the species may not be able to recover. This has been witnessed in species such as the passenger pigeon *Ectopistes migratorius*, which went from being one of the most numerous birds on the planet to being globally extinct in less than 100 years as a result of overhunting and habitat loss.

Classification Systems for Assessing Extinction Risk

The finality of extinction makes it a very powerful motivating force for developing conservation actions to prevent its occurrence, but before we can determine what should be done to protect at-risk species, those species most at risk of extinction must be identified.

Many different systems have been developed to assess extinction risk, each with differing aims and objectives, using a range of demographic and ecological parameters (e.g., Millsap *et al.*, 1990; Master, 1991; Lunney *et al.*, 1996; Cofré and Marquet, 1999; IUCN, 2001; Regan *et al.*, 2004). Some systems are qualitative and strongly based on expert judgment, where threat level is generally inferred from information such as population size, geographic range, threat to the species, or whether the species already benefits from conservation actions. Other systems, however, use quantitative methods that rely on specific rules or point-scoring systems to assign categories of threat. Many systems use a mixture of both quantitative and qualitative attributes. Likewise, some systems are designed purely to evaluate risk of extinction, whereas others focus on ranking species to receive priority conservation attention, and many purport to do both.

This variation is particularly notable at the regional and national levels. Many countries have designed their own classification systems to meet their specific needs by incorporating the parameters they deem most relevant; these needs are sometimes defined as much by legislative and political constraints as by ecological considerations. The resulting lists may reflect extinction risk, rarity, cultural importance, conservation value, population decline, conservation priorities, international responsibility for protection, or a combination of several of these (Miller *et al.*, 2007), yet they are often generally called threatened or endangered species lists. Furthermore, the definitions of categories on these various lists are rarely consistent, so commonly used terms such as

"threatened" and "endangered" sometimes mean generally "at risk of extinction" and sometimes imply a specific level of extinction risk; the precise level of threat for any given term will differ from list to list (de Grammont and Cuarón, 2006). Adding even more confusion, the criteria used are often neither explicit nor transparent and can be significantly subjective (de Grammont and Cuarón, 2006; Feria Arroyo *et al.*, 2009).

Unavoidable though it may be, having multiple classification schemes is inconvenient and even problematic, as assessments made with different methodologies are inherently difficult to compare and are often incompatible (de Grammont and Cuarón, 2006; Miller *et al.*, 2007). This makes understanding and interpreting lists from different countries impossible, which in turn can hamper efforts to consolidate data across regions and impedes large-scale species protection (de Iongh *et al.*, 2003; Miller *et al.*, 2007; Zamin *et al.*, 2010).

Although different classification systems often reflect different objectives, some systems have been found to yield similar threat rankings when applied to the same taxa (O'Grady *et al.*, 2004; Feria Arroyo *et al.*, 2009). However, much variability in the category assigned to a given species still exists, both between systems and within them. Achieving consistency may be highly dependent on who is doing the assessments, as different assessors often come to different conclusions (Regan *et al.*, 2005).

Disagreements between systems can lead to a lack of confidence in species assessments, but many of these differences may be justified as each system has been designed to emphasize different attributes, depending on the purpose for which it was created (O'Grady *et al.*, 2004). It is therefore important to remember the intention of the list when interpreting its results. Nevertheless, species assessments are more likely to be reliable if they are carried out by groups of experts working together, using standardized and transparent protocols, as discussion and peer review are critical to reducing inconsistencies (Regan *et al.*, 2005). Given the immense uncertainty in the population and distribution data available for most species, as well as the important effects that varying attitudes toward uncertainty can have on assessments (Akçakaya *et al.*, 2000), some variability is inevitable. However, using a standard system may facilitate understanding of results and data comparisons across regions (Zamin *et al.*, 2010).

Assessment of Global Species Extinction Risk

The most influential and widely used methodology for evaluating global extinction risk – the IUCN Red List Categories and Criteria (IUCN, 2001) – has been in use and undergone continuous refinement for five decades, evolving from a system based primarily on subjective expert opinion to a more rigorous rule-based system (Mace *et al.*, 2008). The system is designed to reflect the probability of a taxon (most often species, but occasionally subspecies or populations) becoming extinct over a given time period. It aims to provide a standardized, consistent, and transparent method for assessing extinction risk, thereby increasing the objectivity and scientific credibility of the assessments.

Over the past several decades, the IUCN Red List of Threatened Species has developed from a listing of species

assessed *a priori* because of their perceived threatened status to comprehensive or representative assessments of entire taxonomic groups, which include a range of detailed assessment data (Rodríguez *et al.*, 2006). This strong history combined with the thousands of scientists and experts around the world that comprise the IUCN Species Survival Commission network has given the system a unique credibility and recognition worldwide. Today the IUCN Red List is considered one of the most authoritative sources of information on the global conservation status of plants and animals (Lameroux *et al.*, 2003; de Grammont and Cuarón, 2006; Rodríguez *et al.*, 2006).

The IUCN Red List Categories and Criteria classify species by extinction risk, highlighting those species that are most likely to become extinct in the near future given current knowledge of population trends, range and habitat availability, population size and structure, and recent, current, or projected threats acting on the species (see Box 2). The system consists of one set of criteria that are applicable to all species and measure the symptoms of endangerment, not the causes. For example, a species is listed under criterion A based on the rate of population decline over a specific time period, regardless of the causes of the decline. Species can therefore be listed as soon as they display signs of imperilment, even if the cause of threat is unknown. The system is designed to be precautionary but realistic, rather than evidentiary (IUCN SPSC, 2010).

To make listings objective and transparent, extensive documentation is provided to justify the assessment. Each assessed species is cataloged with available information on population size and trends, distribution, ecology and habitat preferences, use and trade information, ecosystem services, threats, and recommended conservation actions. This documentation can be used to inform conservation and policy decisions that involve human activities, development, and business; guide species conservation efforts; direct scientific research; and generate public awareness.

Of course, no assessment system is perfect. In developing a comprehensive methodology applicable to all taxonomic groups across all geographic scales, compromises had to be made (Mace *et al.*, 2008). The system has been criticized for several reasons, including requiring information that is nonexistent or insufficient for many species, incorporating subjective terms that can be misinterpreted and misused, measuring declines over unobtainable or unrealistic time frames (especially for long-lived species), grouping species into broad categories that mask widely differing extinction risk, and having unrealistic threshold values for certain taxa (e.g., Pimenta *et al.*, 2005; Robbirt *et al.*, 2006; Freeman, 2008; Godfrey and Godley, 2008; but see de Grammont and Cuarón, 2006; Miller *et al.*, 2007; Mace *et al.*, 2008). Some analyses have shown that listings tend to be overly precautionary (Heard *et al.*, 2011), and some subjectivity in assessments remains due to data uncertainty and semantic interpretations (Akçakaya *et al.*, 2000). Assessments also come under scrutiny when species of political or economic importance are listed as threatened and when funding opportunities are linked to threatened status (Mace *et al.*, 2008; Gillespie *et al.*, 2011), though this is true of all classification schemes. These complexities notwithstanding, the IUCN system remains the most widely accepted and cited system in use today and

has had a significant influence on biodiversity conservation worldwide.

Assessment of Regional and National Extinction Risk

When it comes to species conservation, the impact of global extinction is clearly more significant than regional extinction, for as long as the species is still present elsewhere, the possibility for recovery always exists. However, loss of local biodiversity can be of major importance to the country or region from which the species disappeared. Moreover, national and regional risk assessments can serve as early warning signs of local impacts, triggering conservation actions that can possibly stave off more widespread declines (Miller *et al.*, 2007), and they may also contribute to informing global conservation efforts and improving our understanding of patterns of global biodiversity loss, especially when the information they contain is incorporated into global conservation efforts like the IUCN Red List (Rodríguez *et al.*, 2000, 2006; Gärdenfors *et al.*, 2001; Brito *et al.*, 2010; Zamin *et al.*, 2010). Incorporating species' conservation status into national and regional decision making is especially important for protection and recovery efforts, because most conservation action and legislation take place at the national and local scale (Miller *et al.*, 2007; Mace *et al.*, 2008; Rodríguez, 2008; Brito *et al.*, 2010).

Significant conceptual differences exist between global and regional extinction risk assessment, primarily because species do not conveniently segregate their populations based on political borders. Biological populations are often distributed across borders, and populations outside the region being assessed can have substantial influence on the long-term survival of populations inside the region, thereby making evaluation of the part of the population resident within a target region very complicated (Gärdenfors, 2001). Deciding which taxa should be assessed adds another layer of complexity, because most countries have nonnative introduced species and nonbreeding migrants and vagrants present within their borders, along with their native historical fauna and flora (Gärdenfors, 2001).

Global conservation status will not always coincide with regional or national conservation status (Gärdenfors, 2001; Gärdenfors *et al.*, 2001; Mace *et al.*, 2008). Certain species may not be at risk globally but can be highly threatened within a particular region (e.g., species at the edge of their geographic range where their population and range size are small). Other species may be threatened globally but be relatively secure within a region; the dugong (*Dugong dugon*), for example, is listed as Vulnerable on the IUCN Red List due to declines throughout at least a third of its global range, yet it appears to be stable throughout much of its Australian range and is not listed as threatened there.

These differences in status at the global and regional levels often cause concern among national assessors, especially when governments have difficulty reconciling these differences in their conservation legislation. The issue may be mitigated by increasing communication and data sharing between global and national assessors (Rodríguez *et al.*, 2000; Miller *et al.*, 2007; Zamin *et al.*, 2010). However, when using different

Box 2**IUCN Red List Categories and Criteria: How does the system work?**

The IUCN Red List Categories and Criteria are used to assess wild populations in their natural range. Species are assigned to one of nine categories based on criteria linked to population trend, population size and structure, geographic range size, amount of occupied habitat, and trends in the amount of habitat (**Box 2 Figure**). Species listed as Critically Endangered, Endangered, or Vulnerable are collectively described as 'threatened'. These three hierarchical categories are defined qualitatively by decreasing probabilities of extinction over increasing time scales and quantitatively by the thresholds in the criteria (Mace *et al.*, 2008).

Box 2 Figure The IUCN Red List Categories and Criteria. Reprinted from Rodrigues ASL, Pilgrim JD, Lamoreux JF, Hoffmann M, and Brooks TM (2006) The value of the IUCN Red List for conservation. *Trends in Ecology and Evolution* 21: 71–76.

*Whichever is longer. Different species with vastly different life histories may be at a similarly high risk of extinction but for different reasons. The five criteria (A–E) in the Red List methodology thus represent different issues that contribute to increased extinction risk such as population decline or a very restricted population or distribution. Not all the criteria will be appropriate for all species, but at least one should capture the symptoms of threat for every threatened species, be it a marine fish with a high rate of population decline due to overexploitation or a terrestrial mollusk with a restricted and declining range as a result of intense habitat loss and degradation. To qualify for listing in any of the threat categories, a species must meet the threshold values for that category for any one of the five criteria, including all relevant subcriteria.

The Red List criteria operate independently of one another, so meeting the thresholds for one criterion does not mean the rules for another criterion also apply. A species listed as Endangered under criterion B may have far more than the 250 mature individuals required to list it as Endangered under criterion D, for example. All taxa are assessed against every criterion, but only one criterion must be met to list the species; in the final listing, all criteria met at the highest level of threat are given.

To prevent erroneous declarations of extinction, the Red List assessment of 'Extinct' is extremely precautionary; the tag 'possibly extinct' has therefore been created to identify those Critically Endangered species that are likely to be extinct, but for which confirmation is required (IUCN SPSC, 2010).

For species listed as Not Evaluated and Data Deficient, no estimation of extinction risk has been made; these species may or may not be threatened and should not necessarily be treated as secure. Similarly, although Least Concern species do not meet any of the criteria for a threatened category, they may be undergoing slow declines that are below the threshold rates or have suffered severe declines too far in the past to qualify for a category of threat. Such species may still require conservation attention.

Particular biological characteristics are incorporated into the criteria to standardize the thresholds across the broad range of species that may be assessed, considering their variable life histories. For example, 'generation length' is used to scale time-based measures – such as a population decline over a given time period – for the different rates at which taxa survive and reproduce. These terms have very specific definitions that must be interpreted correctly in order for the listing to be correct (see IUCN SPSC, 2010).

For more details, see IUCN (2001) *IUCN Red List Categories and Criteria. Version 3.1*. Gland, Switzerland and Cambridge, United Kingdom: IUCN Species Survival Commission, IUCN; Mace GM, Collar NJ, Gaston KJ, *et al.* (2008) Quantification of extinction risk: IUCN's system for classifying threatened species. *Conservation Biology* 22: 1424–1442, and IUCN SPSC (Standards and Petitions Subcommittee) (2010) *Guidelines for using the IUCN Red List Categories and Criteria. Version 8.1*. Available at <http://www.iucnredlist.org/documents/RedListGuidelines.pdf>. Mace *et al.* (2008) give a particularly thorough explanation of the theory and justification of the system, including a detailed description of the logic behind each criterion.

classification systems at different geographic scales, there will inevitably be variability among countries in assessment methods and therefore in species assessments (Rodríguez *et al.*, 2004; Eaton *et al.*, 2005; Miller *et al.*, 2007). An exception is for endemic species assessed using the same classification system at both global and regional scales; these assessments should always concur.

As of 2010, at least 109 countries (~56% of the countries of the world) from virtually every region had produced a national red data book, national red list, or other national list of threatened species, with the fewest coming from Oceania, Africa, and the Caribbean (Figure 1; Zamin *et al.*, 2010). These assessments are carried out by government agencies, non-governmental organizations, or individuals and involve a wide diversity of assessment systems but with few exceptions (e.g., the European Red List initiative) are rarely coordinated across larger regions. This makes large-scale conservation action challenging, as outlined previously.

Regional Assessments Using the IUCN Red List Criteria and Regional Guidelines

The IUCN Red List Categories and Criteria are designed for use at the global level and can lead to incorrect assessments when used at a subglobal scale. This is because small isolated populations often face a higher risk of extinction than large widespread populations (Lande, 1998; O'Grady *et al.*, 2004), so artificially dividing a larger biological population into smaller, more restricted subpopulations located within a political border can cause the individual subpopulations to be assessed as having a higher extinction risk than they actually face (Miller *et al.*, 2007). To resolve this issue, IUCN developed specific guidelines that adapt the criteria for use at the regional level by taking into account the effect that subpopulations outside a region have on the likelihood of that species' extinction within the region (Gärdenfors *et al.*, 1999; Gärdenfors, 2001; Gärdenfors *et al.*, 2001; IUCN, 2003; Miller *et al.*, 2007). These guidelines use data from populations in neighboring regions to determine whether immigration from

outside the region may increase or decrease extinction risk within the region; if necessary, the Red List category is then adjusted by uplisting or downlisting the species accordingly, to more appropriately reflect the long-term extinction risk of the subpopulation being assessed (IUCN, 2003).

At last count, 76 countries were using the IUCN methodology for their national red lists (~39% of all countries; Mace *et al.*, 2008), though not all of these countries employ the regional guidelines as they should (Miller *et al.*, 2007). The system has also been adopted for the European Red List initiative for assessments at the pan-European and EU-27 levels. Despite the quantitative and data-reliant nature of the IUCN methodology – a reason many national assessors claim it cannot be used without modification at the national level (Miller *et al.*, 2007) – it has been used successfully in many countries where data are scarce such as Ecuador (e.g., Tirira, 2011) and Mongolia (e.g., Ocock *et al.*, 2006), as well as for poorly studied taxonomic groups such as Venezuelan invertebrates (Rodríguez and Rojas-Suárez, 2008), Croatian cave-dwelling fauna (Ozimec *et al.*, 2009), and Swedish fungi (Gärdenfors, 2010).

Regional Assessments Based on the IUCN Red List Criteria

Many countries have based their national assessment criteria on the IUCN system, modifying and adding to the IUCN Red List Categories and Criteria as they deem necessary to meet their particular needs, or they have incorporated elements of the IUCN methodology into their national criteria (e.g., Australia (www.environment.gov.au), Austria (Zulka *et al.*, 2003), Canada (www.cosewic.gc.ca, www.sararegistry.gc.ca), Japan (www.biodic.go.jp)).

For example, to list a species under the Australian Environment Protection and Biodiversity Conservation Act (1999), the Threatened Species Scientific Committee may consider a range of biological information to inform its judgments about a species' threat status, including indicative thresholds and qualitative criteria that have been adapted from the IUCN criteria. In Canada, the Committee on the

Status of Endangered Wildlife in Canada (COSEWIC) first assesses the extinction risk of candidate species using a revised version of the IUCN system (having eliminated the Critically Endangered category and changed the name of the Vulnerable category to “Threatened”); however, the government is not obligated to protect threatened species and considers other factors along with threat status when determining which species to legally protect under the Species at Risk Act (SARA).

These systems are effective within the individual countries and often result in strong protective measures for imperiled species. It becomes problematic, however, when a country claims to use the IUCN system but in fact has modified it substantially. It is often difficult to determine which elements of the IUCN methodology have been adopted and how, and this ambiguity can cause substantial confusion. The IUCN regional guidelines were developed to adapt the IUCN system to a subglobal scale and should be used unaltered if the integrity of the system is to be maintained (IUCN, 2003). Of course, many national systems based on the IUCN criteria were developed before the IUCN regional guidelines were published in an effort to fit the IUCN Red List Categories and Criteria to the national scale, and they are now cemented so firmly in governmental legislation that amendment is difficult.

Other Approaches

A few countries and organizations have created their own unique systems for evaluating and listing threatened species. Perhaps the most well known is the United States’ Endangered Species Act (ESA); passed in 1973, the ESA is one of the oldest and strongest national laws created to protect imperiled species. The ESA lists species in one of two categories of risk: “endangered” species are in danger of extinction throughout all or a significant portion of their range, whereas “threatened” species are likely to become endangered within the foreseeable future. However, the listing criteria are notably vague, and placement of species in a given category depends entirely on expert judgment. Species are listed based on any of the following factors (ESA, Section 4(a)(1)):

1. the present or future destruction, modification, or curtailment of its habitat or range;
2. overutilization for commercial, recreational, scientific, or educational purposes;
3. disease or predation;
4. the inadequacy of existing regulatory mechanisms; and
5. other natural or manmade factors affecting its continued existence.

Although the ESA lists species “solely on the basis of the best scientific and commercial data available” (ESA, Section 4(b)(1)(A)), in reality political and economic concerns often come into play when deciding whether to list a species (Shelden *et al.*, 2001), as is true in many countries. Listing a species has substantial impact, as the ESA affords direct legal protection to all listed species and their habitats on both publicly and (except for plants) privately owned lands. Federal agencies, private landowners, and citizens are prohibited from harming these species in any way, including damaging important habitats, though permits allowing such

activities can be obtained and mitigation plans can be developed to compensate for damage done to listed species or their habitats.

Many species no doubt require such strict measures for their survival, and the ESA is commendable for providing such rigid protection, but the unfortunate result has been that some commercially important or politically sensitive species have not been listed, specifically to avoid the issue of enforcing this protection. The status of hundreds of species that are likely at risk of extinction thus remains undefined, preventing them from benefiting from nonlegally binding protection measures – a regrettable consequence of combining legal protection with threatened status assessment (see Box 1).

Another influential classification scheme, the NatureServe Conservation Status methodology, has been used extensively over the past two decades by a network of natural heritage programs and conservation data centers throughout the Western hemisphere. NatureServe assessments provide information on global, national, and subnational (state or province) conservation status for North American animals, plants, and fungi; ecological communities; and ecological systems (collectively called *elements* of biodiversity) (Faber-Langendoen *et al.*, 2009; Master *et al.*, 2009). Although the system includes global assessments, it has been designed primarily for use in the US and Canada.

In the NatureServe system, “elements” are assessed against 10 biological or external factors, grouped into three general categories, that may affect their ability to persist in the wild (Faber-Langendoen *et al.*, 2009):

- *Rarity*: Population Size, Range Extent, Area of Occupancy, Number of Occurrences, Number of Occurrences or Percent Area with Good Viability/Ecological Integrity, and Environmental Specificity.
- *Trends*: Long-term and Short-term Trend in population size or area.
- *Threats*: Threat Impact (generated by considering the scope and severity of the major threats), and Intrinsic Vulnerability (used only if Threat Impact is unknown).

A numerical score is computed based on weightings assigned to each factor and some conditional rules, which is translated to a final rank. This rank can be adjusted if the assessor deems it necessary, though the reasoning must be documented. The final assessment is recorded using a scale of 1–5, G1 being critically imperiled on a global scale and G5 being globally secure; a prefix of N or S indicates national (N1–N5) and subnational assessments (S1–S5). An element can be listed across multiple categories and at several geographic scales; for example, the knobby brain coral (*Diploria clivosa*) is listed as G4G5S2, indicating that there is uncertainty whether it is secure or apparently secure at the global level, whereas it is imperiled at the subnational level (in this case, Florida). Several other symbols can be added to the final rank, such as Q for questionable taxonomy or U for unrankable due to insufficient or conflicting data. There are also categories for extinct (GX/NX/SX) and possibly extinct (GH/NH/SH).

Like the IUCN system, the purpose of the NatureServe conservation status ranks is to classify species by extinction risk in a scientific, objective, and consistent manner. Efforts have

recently been made to standardize the definitions for shared terms in the IUCN and NatureServe methodologies, allowing information to be communicated between organizations and countries and the same data to be used for either system (Master *et al.*, 2009).

Applications of Threatened Species Assessments

From its origins as a general interest in rare and declining wildlife, the science of threatened species assessment has blossomed into a massive conservation theme with far-reaching influence on conservation on the ground (and in the water). Although threat status alone should not determine conservation priorities (Possingham *et al.*, 2002; Rodrigues *et al.*, 2006; Miller *et al.*, 2006, 2007; see Box 1), threatened species lists have become one of the most important tools in the conservationist's toolbox, with threatened species assessment data being widely incorporated into international conservation policies and priority-setting strategies.

Determining the Status of Biodiversity

Threatened species assessment data can provide important insights into not only the status of the individual species assessed but also the overall status of biodiversity and geographical patterns of threat, which is essential information for monitoring and directing effective conservation action.

For example, IUCN has evaluated the global threat status of 59,508 species of animals, plants, and fungi (IUCN, 2011). Since 1500, nearly 800 species have been documented as having gone Extinct, whereas 64 are Extinct in the Wild (IUCN, 2011). The best estimates of the proportion of threatened species among completely assessed groups ranges from 0% to 63% (Table 1). Alarmingly, nearly one-fifth (19%) of extant vertebrate species are threatened with extinction (Hoffmann *et al.*, 2010); the true value of this estimate falls between 16% (assuming no Data Deficient species are threatened) and 33% (assuming all Data Deficient species are threatened). Although only 1% of described invertebrate species have been assessed, those few groups that have been completely assessed generally show high levels of threat (Table 1). Plants fare no better, especially the ancient conifer and cycad lineages (Table 1). Though trends in completely assessed plant groups to date do not likely represent the overall status of plants (Hilton-Taylor *et al.*, 2009), preliminary results from a representative sample of plant species suggest that 22% may be threatened (<http://threatenedplants.myspecies.info/>), a figure similar to the proportion of threatened vertebrates.

Threatened species lists can also give insight into the status of different ecosystems. Freshwater ecosystems appear to be particularly at risk, as demonstrated by the threat levels of amphibians, freshwater crabs, and crayfish (Table 1); although dragonflies are also freshwater dependent, they are less likely to become highly threatened for a variety of reasons (see Clausnitzer *et al.*, 2009). Likewise, some marine groups exhibit high levels of threat – for example, 33% of cartilaginous fish and corals (IUCN, 2011), 36% of marine mammals (Schipper *et al.*, 2008), 27.5% of seabirds, and 86% of marine turtles

(Polidoro *et al.*, 2009). This is unsurprising considering the large number of overlapping threats marine species face: high and often unregulated fishing pressure, rapid coastal development, pollution, and changing ocean conditions under climate change (Polidoro *et al.*, 2009). Nonetheless, much is still unknown about threat status in marine species, and many groups exhibit notably high levels of data deficiency (Table 1).

Threatened species are concentrated in tropical regions, and these concentrations are disproportionately high even when accounting for their high overall species richness, as exemplified by marine and terrestrial vertebrates (Figure 2). This is not surprising given that these areas combine high species richness, high endemism, and high human pressure (Schipper *et al.*, 2008; Hoffmann *et al.*, 2010). Data Deficient species are also highly concentrated in the tropics (Hoffmann *et al.*, 2010); in regions where land and water resources are being rapidly degraded, many DD species may be dangerously close to extinction (Schipper *et al.*, 2008). Plant and invertebrate geographic threat patterns appear to be broadly similar to those of vertebrates (e.g., Carpenter *et al.*, 2008; Clausnitzer *et al.*, 2009; Collen *et al.*, 2009; Polidoro *et al.*, 2010).

Threatening processes themselves are distributed non-randomly worldwide. For example, Li and Wilcove (2005) found that the most pervasive threat to vertebrates in the US is habitat destruction, which affects more than 92% of imperiled species. In China, however, overexploitation is the major threat to vertebrates, affecting 78% of imperiled species, followed by habitat destruction (70%). Maps correlating the presence of threatened species with the primary threats affecting them can be especially informative for conservation decision making (Figure 3).

Informing Conservation Action for Individual Species and Guiding Scientific Research

Threatened species lists should be supported by additional data that justify the species assessments (though this is not always the case); these data can be used to help develop conservation programs and guide scientific research and monitoring to fill knowledge gaps. For example, the most important anthropogenic drivers of threat for biodiversity today are habitat destruction, introduction of alien species, overexploitation, disease, and climate change (Mace *et al.*, 2005); the significance of different threats, however, varies both within and between taxonomic groups (Figure 4). The IUCN Red List includes a description of the threats affecting listed species and a series of proposed conservation actions to mitigate those threats, thus providing direct recommendations for species-specific measures to be taken (Baillie *et al.*, 2004; Rodrigues *et al.*, 2006). On oceanic islands, for instance, eradication of introduced predators is often a crucial step in restoring native species that have been decimated by these hungry invaders (Ortiz-Catedral *et al.*, 2009).

It is encouraging that several studies have shown that active conservation can be effective in improving the status of biodiversity (Sodhi *et al.*, in press). Hoffmann *et al.* (2010), for example, found that despite an overall decline in vertebrate

Table 1 Number of species in each IUCN Red List category and proportion of threatened species for all vertebrates and all major completely or randomly assessed invertebrate and plant groups. IUCN Red List categories: EX, Extinct; EW, Extinct in the Wild; CR, Critically Endangered; EN, Endangered; VU, Vulnerable; NT, Near Threatened; LC, Least Concern; DD, Data Deficient. Threatened includes Vulnerable, Endangered, and Critically Endangered Species. Asterisks indicate groups in which estimates are derived from a randomized sampling approach. Lower estimates of percent threatened assume no DD species are threatened, upper estimates assume all DD species are threatened, and best estimates assume DD species are threatened in the same proportion as data-sufficient species

All other data from IUCN (2011) *IUCN Red List of Threatened Species. Version 2011.1*. Available at: <http://www.iucnredlist.org>

Figure 2 Residuals of the relationship between total number of vertebrate species and total number of threatened vertebrate species per cell, where positive values (red) represent cells with higher threat than expected for their richness alone, and negative values (gray) represent cells with equal or lower threat than expected for richness alone. Reproduced from Hoffmann M, Hilton-Taylor C, Angulo A, *et al.* (2010) The impact of conservation on the status of the world's vertebrates. *Science* 330: 1503–1509, with permission from AAAS.

Figure 3 Geographical pattern of the dominant causes of rapid decline in amphibian species: overexploited (shades of blue); reduced habitat (shades of green); and enigmatic decline (shades of red). Where two threat types overlap in the same 1° cell, the color referring to the threat type with the larger number of rapidly declining species in that cell is indicated on the map. Intermediate colors are shown in cases of equal numbers of species experiencing two types of decline in the same cell, as shown in the key. Darker colors correspond to larger numbers of rapidly declining species of any type (not just of the dominant type in the cell in question). Reproduced from Stuart SN, Chanson JS, Cox NA, *et al.* (2004) Status and trends of amphibian declines and extinctions worldwide. *Science* 306: 1783–1786, with permission from AAAS.

threat status, 64 vertebrate species listed on the IUCN Red List improved in status as a result of conservation actions; without these conservation successes, vertebrate threat status would have declined by at least an additional 20%. Monitoring changes in the status of targeted species as a result of specific

conservation measures can thus help measure the effectiveness of those actions.

Threat status is one of the key criteria for identifying Evolutionarily Distinct and Globally Endangered (EDGE) species, which are phylogenetically unique species that are frequently

Figure 4 Proportion of threatened vertebrates affected by different major threats. Asterisks indicate groups in which estimates are derived from a randomized sampling approach. Data from Hoffmann M, Hilton-Taylor C, Angulo A, *et al.* (2010) The impact of conservation on the status of the world's vertebrates. *Science* 330: 1503–1509.

overlooked in existing conservation frameworks (Isaac *et al.*, 2007). The EDGE program aims to maintain genetic diversity by focusing conservation attention, resources, and research on threatened species that represent a significant amount of unique evolutionary history.

Good knowledge of a species' population, distribution, biology, threats, and conservation needs and regular monitoring of its threat status over time are essential requirements for any effective conservation strategy. Not enough data exist, however, to complete threat status assessments for many species, some of which may be highly threatened; considerable information gaps remain among even the most well-studied species (Hoffmann *et al.*, 2008). These data deficiencies highlight areas where further study is needed to build baseline information on population size, range, habitat and ecology, threats to species, and the trends in all these measures (Baillie *et al.*, 2004; Hoffmann *et al.*, 2008). Data Deficient species therefore represent high research priorities (Butchart and Bird, 2009). Compiling threatened species lists can reveal information gaps and stimulate data collection in the field (Miller *et al.*, 2007), especially in highly diverse regions that have been poorly studied, where a significant proportion of Data Deficient species are found (Baillie *et al.*, 2004; Hoffmann *et al.*, 2010).

Informing Identification of Important Sites for Biodiversity

Given that habitat destruction is the primary threat for most terrestrial and freshwater species (Baillie *et al.*, 2004), one of the most imperative conservation responses is establishing

protected areas to safeguard the habitats in which these species live (Bruner *et al.*, 2001). This would be ideally accomplished by identifying comprehensive networks of protected sites that collectively help to minimize biodiversity loss (Pressey *et al.*, 1993; Margules and Pressey, 2000). Strong political agreements are helping to drive this work; for example, Target 11 of the Convention on Biological Diversity's 2011–2020 Strategic Plan specifically calls for conservation of terrestrial, inland water, coastal, and marine areas of importance for biodiversity, through comprehensive, representative, and well-connected systems of effectively managed protected areas.

Biodiversity assessment data like that found on threatened species lists can be used to help determine gaps in the existing protected area network. Rodrigues *et al.* (2004) used species distribution maps to assess how effectively terrestrial vertebrates are represented in the existing protected area network and identify gaps in coverage; they found that 20% of globally threatened species were not covered in any part of their range, compared to 12% of all species analyzed. Such analyses are also relevant at regional (e.g., Rondinini *et al.*, 2005) and national (e.g., Jaffre *et al.*, 1998) scales.

Various initiatives exist for identifying site-scale conservation targets essential to maintaining biodiversity, which can help to strategically fill these gaps. For instance, European Natura 2000 sites are selected specifically to ensure long-term survival of Europe's most valuable and threatened species and habitats. Presence of threatened species is one of the key criteria for designating Ramsar wetland sites, Ecologically and Biologically Significant Areas (specifically for marine species; CBD COP 9 Decision IX/20), Important Bird Areas (IBAs; Osieck and Mörzer Bruyns, 1981), and important plant

areas (IPAs; Anderson, 2002), among others. The latter two initiatives fall under the umbrella of the Key Biodiversity Areas (KBA) approach (Eken *et al.*, 2004; Langhammer *et al.*, 2007), which aims to identify globally important sites to ensure the persistence of biodiversity based on the presence of threatened, congregatory, or range- or biome-restricted species.

A particularly important subset of KBAs are Alliance for Zero Extinction (AZE) sites (Ricketts *et al.*, 2005), which hold the last remaining population of Critically Endangered or Endangered species as listed on the IUCN Red List. AZE sites reflect the topmost tier of KBA sites where action is urgently needed (Figure 5). Several dozen countries have identified KBAs as part of their commitment under the Convention on Biological Diversity's Program of Work on Protected Areas (Brooks, 2010), and the process is underway in many more (Langhammer *et al.*, 2007). A regional KBA approach has been piloted in Turkey, where the IUCN Red List and nationally

listed threatened species were used to identify KBAs at both the global and regional scale (Eken *et al.*, 2004).

Policy-Based Actions

Concerns over the mounting biodiversity crisis and the associated impacts on human well-being have led to the creation of international conservation policies with far-reaching aims. The most influential of these is arguably the Convention on Biological Diversity (CBD): in 2002, the 188 CBD government parties agreed an explicit mandate for improving the status of threatened species, by "significantly reducing the rate of biodiversity loss by 2010." Known as the 2010 Target, this ambitious goal inspired a flurry of conservation activity as signatory countries attempted to both meet the target and devise methods for evaluating progress toward this goal.

Figure 5 Site-scale conservation priorities in Madagascar, reflecting the nested and complementary nature of sites identified at different scales. Key Biodiversity Areas (KBA; $n=117$) identified from the distributions of threatened species in eight taxonomic groups (mammals, birds, amphibians, freshwater fish, reptiles, arthropods, gastropods and plants); Important Bird Areas (IBA; $n=78$), the avian subset of KBAs; Alliance for Zero Extinction (AZE) sites ($n=16$) contain the entire population of Critically Endangered or Endangered species. Inset: urgent priorities (pink grid squares) identified at a larger scale for expanding the network of protected areas in Madagascar, ranked according to an extinction risk index (data for mammals, birds, amphibians, and turtles). Reprinted from Hoffmann M, Brooks TM, da Fonseca GAB, *et al.* (2008) Conservation planning and the IUCN Red List. *Endangered Species Research* 6: 113–125, with permission from Inter Research.

Although the 2010 Target was not met (Mace *et al.*, 2010), the 20 “Aichi Targets” adopted as part of the 2011–2020 CBD Strategic Plan (COP 10 Decision X/2) built on the original goal. Information from threatened species lists can be used to measure progress in at least 13 of the 20 Targets (*see* Importance for Monitoring State of Biodiversity: Developing Indicators of Global Biodiversity Status). Achieving Target 12 (extinction and decline of threatened species is prevented and their status improved) in particular will depend on understanding threatening processes and addressing their impacts successfully. National CBD commitments will result in increasing efforts to protect and recover threatened species as the new strategic plan is translated into CBD-mandated National Biodiversity Strategies and Action Plans.

Assessment data from threatened species lists and change in the status of threatened species can inform several other international environmental agreements. For example:

- The CBD 2010 Target was adopted into Target 7b of the United Nations Millennium Development Goal 7 (MDG 7): Ensure environmental sustainability.
- Appendix I of the Convention on Migratory Species (CMS) lists migratory species threatened with extinction; parties to the convention strive to strictly protect these species and their habitats and remove any obstacles to their migration.
- Targets 2, 7, and 8 of the CBD Global Strategy for Plant Conservation call for the status assessment of all known plant species and *in situ* or *ex situ* conservation of 75% of threatened species.
- One criterion for designating a wetland for special protection under the Ramsar Convention is if the wetland “supports vulnerable, endangered, or critically endangered species” as defined by national or international threatened species programs (e.g., national threatened species lists, the IUCN Red List) or frameworks (e.g., CMS appendices).
- The Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) aims to ensure that international trade in specimens of wild animals and plants does not threaten their survival; strict controls on the trade of species listed on the three appendices are established, with species on Appendix I (species threatened with extinction that are or may be affected by trade) afforded the most protection (trade is permitted only in exceptional circumstances).

It is worth discussing CITES in more detail, as many misinterpret it to be a method for measuring extinction risk. CITES lists species in three appendices according to their conservation status and the risk they face from international trade. The CITES appendices are not traditional lists of threatened species, as they do not aim purely to report vulnerability to extinction; rather, they highlight those species for which trade may jeopardize their survival. Only those species that are demonstrably threatened by international trade should be listed on CITES, though these species are often absent from CITES appendices, whereas others not threatened by trade are erroneously listed on CITES (Stuart *et al.*, 2008). Furthermore, CITES criteria simply provide guidance; there is no obligation to list a species that meets the criteria. Consequently, listing a species under CITES often sparks hot

debate, especially if the decision is controversial or involves a species with a lucrative international trade market. Many argue that CITES is more political than conservation-oriented, but ultimately the fact that thousands of species are afforded international protection due to their placement on the CITES appendices makes the system immensely influential in the fate of threatened species that are internationally traded.

The European Union has pioneered the implementation of conservation policies at the regional level, helped no doubt by their cohesive political stature. Since 1982, European signatory countries to the Convention on the Conservation of European Wildlife (the Bern Convention) have committed to conserving wild flora and fauna, with particular emphasis on “endangered and vulnerable” species and habitats. The Birds and Habitats Directives followed from the Bern Convention and required European Union member states to maintain and restore favorable conservation status of the endangered and vulnerable species listed in their annexes. This is often achieved through the designation of Natura 2000 sites; outputs of the European Red List initiative can be used to inform placement of species on the directives as well as Natura 2000 site identification. Donald *et al.* (2007) found that the Birds Directive has brought demonstrable benefits to European bird populations. Inspired by the CBD 2010 Target, in 2003 European ministers of environment adopted the even-stricter target of halting biodiversity loss by 2010. Although these conservation aims have not always been met, the European example shows that international policies can be effective in addressing conservation issues over wider regions (Donald *et al.*, 2007).

Biodiversity assessment data can also be used to inspire and inform national development policies and legislation to protect species and the sites they inhabit (e.g., in the areas of land-use planning, transport, energy, poverty reduction strategies, and national biodiversity strategies and action plans) (Rodrigues *et al.*, 2006). Moreover, in many countries there is a direct connection between threatened species lists and conservation legislation, as exemplified by the US Endangered Species Act (*see* Classification Systems for Assessing Extinction Risk). As important and influential as national conservation policies are, they must be crafted carefully; basing protective legislation directly on threat categories can have unanticipated consequences, such as when governments prohibit access to threatened species and thus impede their scientific study (Rodrigues *et al.*, 2006), and may not lead to optimal expenditure of resources (Possingham *et al.*, 2002).

Importance for Monitoring State of Biodiversity: Developing Indicators of Global Biodiversity Status

Since the adoption of the CBD 2010 target, much effort has been dedicated to developing indicators capable of measuring changes in the state of biodiversity over time, assessing the impact of policy and management responses, and identifying priorities for action (Walpole *et al.*, 2009). One such indicator is the IUCN Red List Index (RLI; Butchart *et al.*, 2004, 2005, 2007), which monitors trends in species’ threat status and is thus a key measure of whether the rate of biodiversity loss is escalating or being reduced. The RLI was adopted as one of the 22 headline indicators to measure progress toward the CBD

2010 Target and subsequently incorporated into other global policies (e.g., MDG 7, CMS) and regional initiatives (e.g., Streamlining European Biodiversity Indicators, SEBI-2010).

The RLI shows trends in the overall extinction risk of species based on the number of species that move between IUCN Red List categories over time as a result of genuine improvements or genuine deterioration (i.e., category changes due to improved knowledge or revised taxonomy are excluded) (Butchart *et al.*, 2004, 2007). It can be calculated for any set of species that has been assessed at least twice.

At the global level, a RLI of comprehensively assessed groups on the IUCN Red List shows that the rate of biodiversity loss is increasing (Butchart *et al.*, 2010; Secretariat of the Convention on Biological Diversity, 2010); coral species in particular are moving rapidly toward extinction, while amphibians are, on average, more threatened than birds, mammals, or corals (Figure 6(a)). At a national level, the situation in Sweden appears less grim (Figure 6(b)): the rate of biodiversity loss is relatively constant for most species and even improving for vertebrates, though ultimately 1942 species are still at risk of extinction (Gärdenfors, 2010).

The RLI can and has been used to monitor trends in biodiversity status at the regional (e.g., IUCN, 2010), national (e.g., Gärdenfors, 2010), and subnational (e.g., Quayle *et al.*, 2007) levels (Bubb *et al.*, 2009). It can also be disaggregated by taxonomy, body size, or ecology or by habitat, ecosystem, region, or biogeographic realm (e.g., Butchart *et al.*, 2005; Stuart *et al.*, 2008; Hilton-Taylor *et al.*, 2009; Hoffmann *et al.*, 2011); threat (Butchart, 2008; McGeoch *et al.*, 2010); or benefit to humans (e.g., internationally traded food and medicine species; Butchart *et al.*, 2010). A sampled RLI approach has been developed, based on the rate at which a stratified sample of species moves through the IUCN Red List categories (Baillie *et al.*, 2008), which will enable us to track conservation status across a broader, more representative range of taxonomic groups.

Resource Allocation

Demand for human and financial resources to support conservation efforts far outweighs the supply. Given this harsh reality, conservation agencies and funding bodies often use species' threat status to help focus priorities for global conservation resources and to guide conservation investment. For example, IUCN Red List data have been incorporated into the system for resource allocation (which determines how much money each focal country can receive) of the Global Environment Facility (GEF), the largest funder of projects to improve the global environment (GEF has allocated \$9.5 billion (US) since 1991). Numerous funding organizations draw

on threatened species information to decide where to allocate resources, such as the \$130 million (US) Critical Ecosystem Partnership Fund, the \$6 million (US) Mohammad bin Zayed Species Conservation Fund, and the \$4 million (US) Conservation Leadership Program.

One downside to using threat category to inform resource allocation is that species in lower threat categories and Data Deficient species may be disregarded when allocating resources for conservation (Gillespie *et al.*, 2011). Allocating the most funds to the most-threatened species could in theory also fail to maximize conservation returns, as less-threatened taxa can often be recovered with a smaller investment, leaving more money to go around (Possingham *et al.*, 2002), although this concern may be offset by the fact that most threatened species live in those areas of the world where conservation interventions are cheapest (*see* Determining the Status of Biodiversity). And despite the sums spent on conservation annually, the amount required to even begin safeguarding biodiversity remains a distant goal (though reachable through modification of government expenditure) and a disproportionate amount is spent in wealthy countries where the number of threatened species is lower (James *et al.*, 1999, 2001).

Informing Environmental Safeguards

Economic development and poverty alleviation have historically been considered incompatible with biodiversity conservation. Today, however, protecting and conserving biodiversity, including the services and products that natural habitats provide, and sustainably managing natural resources are increasingly being recognized as fundamental to lasting sustainable development. Appropriate environmental safeguards – tools and policies specifically designed to minimize the level of environmental risk (including offsetting any inevitable environmental impacts) and to maximize the environmental benefits of development projects – are essential to guaranteeing that biodiversity conservation and other environmental objectives are integrated into development plans.

The loss of biodiversity undermines not only the species and habitats directly affected but also the human communities that rely on natural systems for their livelihoods (Millennium Ecosystem Assessment, 2005). Leading development banks and financial institutions such as the World Bank, European Bank for Reconstruction and Development, and GEF have adopted policies that ensure the projects they fund support and promote the protection and restoration of natural environments; data from threatened species lists can feed directly into these policies. For example, Performance Standard 6 (Biodiversity Conservation and Sustainable Management of

Figure 6 IUCN Red List Indices (RLI) of species survival, showing proportion of species expected to survive into the near future without additional conservation action. An RLI value of 1 indicates that all species are Least Concern, whereas a value of 0 indicates that all species have gone Extinct. A downward trend indicates that the expected rate of species extinctions is increasing (i.e., the rate of biodiversity loss is increasing); a horizontal line implies that extinction risk is constant; an upward trend means that the rate of biodiversity loss is being reduced. (a) The global extinction risk of birds, mammals, amphibians, and reef-forming corals is increasing, with corals showing the most dramatic declines. (Source: IUCN. Reprinted with permission from Secretariat of the Convention on Biological Diversity (2010) *Global Biodiversity Outlook 3*. Montréal: Secretariat of the Convention on Biological Diversity.) (b) The expected rate of extinctions in Sweden is improving somewhat for vertebrates but declining for vascular plants; the rate of biodiversity loss for other taxonomic groups remains relatively unchanged. (Reprinted with permission from Gärdenfors U (ed.) (2010) *Rödlistade arter i Sverige – The 2010 Red List of Swedish Species 2010*. SLU, Uppsala: ArtDatabanken.)

Living Natural Resources) in the International Finance Corporation's Policy and Performance Standards on Social and Environmental Sustainability explicitly makes reference to threatened species under the IUCN Red List criteria, prohibiting any project activity that leads to measurable adverse impacts or a direct reduction in any globally or regionally listed Critically Endangered or Endangered species (IFC Performance Standard 6(17)).

Protocols for ensuring environmental stewardship in project development have also been widely incorporated into international, national, and state laws and treaties. Article 14 of the CBD, for example, specifically calls for parties to implement environmental impact assessment (EIA) procedures. Conducting an EIA during the planning stage of a project life cycle has become standard practice for many companies and organizations, including national, state, and local governments. Though it is often difficult to predict the impacts of development on biodiversity (Meynell, 2005), whether a project is likely to affect threatened species or their habitats is generally one key consideration in deciding whether the project may proceed or how to mitigate the environmental impacts the project may have.

Challenges and Future Directions

We have come a long way toward understanding and measuring extinction risk in the past century, and we are well on our way to integrating this knowledge into proactive conservation policies and programs. However, some tough challenges remain to be met if we are to fully understand how and where the multiple drivers of threat impact different species and how best to respond to minimize biodiversity losses.

Addressing both taxonomic and geographic knowledge gaps is a huge priority. Data remain scarce for many taxonomic groups and those data that do exist are biased toward terrestrial species and temperate zones (Mace *et al.*, 2005), hampering efforts to measure the state of biodiversity worldwide. Most threatened species lists (including the IUCN Red List) lack important information on plants, invertebrates, fungi, and freshwater and marine species (Stuart *et al.*, 2010), whereas national lists are missing entirely from many countries, especially in Oceania, Africa, and the Caribbean (Zamin *et al.*, 2010). The Sampled Red List approach (Baillie *et al.*, 2008) is a big step toward addressing taxonomic knowledge gaps, but expanding global biodiversity datasets to meet the geographic gaps will require enlisting many new experts worldwide (Stuart *et al.*, 2010).

Long-term investment in iterative biodiversity assessment is needed at all levels. As knowledge of biodiversity increases and intensifying threats change the ecological landscape, our measures of species' extinction risk can and will change dramatically. If we hope to develop effective mechanisms for protecting and recovering species and to monitor the conservation actions we put in place, then we must stay abreast of changes in threat status. Establishing a representative "barometer of life" (Stuart *et al.*, 2010) and maintaining and improving assessment data will require a sincere commitment not only by the scientific community but also by the governments and funding bodies that support these efforts (e.g.,

approximately \$400,000 (US) year⁻¹ is needed to maintain the IUCN Red List mammal data set alone; Hoffmann *et al.*, 2011).

Our long-term knowledge of trends must catch up with our knowledge of status. Despite various data gaps, we have a substantial body of knowledge that can provide insight into the state of biodiversity today. However, we are only beginning to gauge how this status is changing over time, additional indicators to measure these trends are needed. Monitoring trends in status is increasingly important for determining whether we are effectively reducing the rate of biodiversity loss, but to do so we need a time series of comparable measures (Mace *et al.*, 2005). This requires that assessment methods as well as the groups being assessed be consistent over time, and links to the need for repeated and consistent assessments.

Understanding the multiple and interacting impacts that climate change may have on species and how these impacts affect extinction risk is another critical task (Akçakaya *et al.*, 2006). Despite the burgeoning literature on potential and realized climate change impacts, on-the-ground evaluations of vulnerability assessments and predictions are rare. IUCN has begun to address this issue, adding codes describing various climate change threat types to its assessment protocols and updating guidance on how to interpret the Red List Categories and Criteria in a climate change context (IUCN SPSC, 2010). Methods for assessing species' climate change susceptibility, designed to be used during or complementary to extinction risk assessment, are also emerging (Foden *et al.*, 2009; Young *et al.*, 2011). Evaluating the accuracy of extinction risk predictions based on climate change impacts is an important new frontier.

Threatened species lists at all spatial scales would benefit from increased communication and cooperation between countries, as well as better linkages between national and global assessment efforts (Rodríguez *et al.*, 2000; Miller *et al.*, 2007). The national "red listing" network is rapidly expanding, and with it interest in using the IUCN methodology to assess species extinction risk. Integrating the diffuse network of national assessors into the global IUCN Red Listing process could bring about the dual benefits of expanding information on the world's threatened species and building local scientific capacity for generating and using these data to effect conservation action on the ground (Rodríguez, 2008). Existing experts such as IUCN Species Survival Commission members can play an important role in helping to build and strengthen such a network by acting as advisers to national assessment efforts. Regular training of both global and national assessors is imperative to maintain and improve assessment rigor and consistency, as well as increase awareness of the multiple issues that affect extinction risk assessment. In addition, standardizing classification systems between countries and with the IUCN Red List would help facilitate knowledge transfer and allow for the development of coordinated strategies for data collection and biodiversity conservation across wider regions.

Finally, our biggest challenge over the next few decades will be to respond to the massive ecological shifts already underway and to stem the rising tide of extinction. The information contained in threatened species assessments will be fundamental to informing our progress and directing conservation strategies. Tackling the many drivers of threat to reduce rates of biodiversity loss will be key to success but is undoubtedly the

most difficult challenge that lies ahead. Yet considering the rapid expansion of conservation science and the explosive growth of threatened species lists in the past several decades, we should be up to the challenge. For our own future as much as for the future of the biodiversity on our planet, it is imperative that we get it right.

Glossary

Allele Variant of a gene at a given locus.

Chain-termination sequencing Method for DNA sequencing that employs four reactions, one for each nucleotide, and terminates the copy at each occurrence of a given base.

Coalescent Looking back in time through a genealogy to where two genetic lineages come together in a common ancestor.

DNA slippage Polymerase error leading to a change in the length of a simple repetitive sequence.

Genetic drift Stochastic changes in allele frequencies in a finite population.

Genetic load Extent to which an individual is inferior to the best possible individual in the population as a consequence of the genes it contains.

Microarray Collection of microscopic DNA spots attached to a solid surface; used in the analysis of gene expression or genetic variation.

Microsatellite locus Sequence of 2–4 base pairs repeated end on end.

Neutral theory That the majority of nucleotide substitutions result from the random fixation of neutral or nearly neutral mutations.

Phenotype Observable characteristics or traits of an organism.

Beginnings

Charles Darwin understood that the motive force of evolution must be a process that reflected the diversity of individuals within populations of a given species. Inspired by the writings of economist Thomas Robert Malthus, Darwin saw that the exponential potential of reproductive growth would be kept in check by limited resources. As part of that process, some individuals would be better suited to survive and reproduce than others. These ideas are at the core of what we think of as conservation genetics today. An essential belief is that diversity in populations must be retained to allow adaptation to changing environments by the process Darwin called “natural selection.” Diversity at the population level is the raw material of evolution by natural selection, and the confirmation of this has been evident to animal and plant breeders for a long time. Even so, it was not until the mid-1960s that the reality of intraspecific diversity at the population level became widely appreciated. The turning point was a study by Hubby *et al.* (1966) in which they described the gel electrophoresis of enzyme variants, referred to as “allozymes.” Recognizing that proteins (including enzymes) have charge properties that affect their migration through an electrical field, and that through the manipulation of the catalytic properties of enzymes a dye can be produced to reveal the presence of a specific gene product (a “polypeptide”), they provided a simple and reproducible method that could reveal molecular genetic diversity at the population level.

In no time, keen population geneticists were grinding up pretty much anything they could get hold of and producing a burgeoning record of diversity in natural populations for an expanding range of taxa. Soon the first studies that explicitly considered the importance of conserving genetic diversity were published. In the late 1960s and early 1970s, these studies were predominantly about conserving genetic resources for their economic value. For example, Orrewing (1969) wrote of developing a program of “genetic improvement” for

commercial forests in British Columbia, and Turner (1971) wrote about the conservation of genetic resources in domestic animals. These studies extended to various aspects of plant and animal breeding and included studies associated with fisheries (e.g., Moller, 1969). However, even at this early stage, there were studies that concerned themselves primarily with the management of natural populations – for example, a study on the genetic diversity of declining peregrine falcon populations (White, 1969). A significant contributor to this early work was Otto Frankel, by then a septuagenarian. He had devoted his earlier career to plant breeding and initially built on that experience. But in 1974, Frankel published a paper that spelled out in the clearest of terms a dominant ethos of modern conservation genetics. In a paper titled “Genetic Conservation: Our Evolutionary Responsibility,” he wrote, “Wild species, increasingly endangered by loss of habitats, will depend on organized protection for their survival. On a long-term basis this is feasible only within communities in a natural state of continuing evolution, hence there is an urgent need for exploration and clarification of the genetic principles of conservation.” (Frankel, 1974).

This set the stage and the tone for the next decade or so. The emphasis was very much on endangered species and on documenting levels of diversity toward a better understanding of the implications of lost diversity. Proponents of the neutral theory of evolution were describing not only the role of genetic drift in the loss of diversity but also the relationship between population size and the rate at which diversity was lost (Kimura, 1968; Nei *et al.*, 1975). Small populations lose diversity quickly (at a rate of $1/2N$ each generation), so exploited populations were investigated for evidence of an anthropogenic impact. In 1974, Michael Bonnell and Robert Selander investigated genetic diversity at 24 allozyme loci for the northern elephant seal (*Mirounga angustirostris*) and found no diversity at all. Elephant seals were abundant off California in the 1970s and their populations were growing fast, but 100 years earlier the species had almost vanished. These seals had

been hunted for their blubber to produce oil for lamps among other products, and their nature made them easy to approach and therefore easy prey. The last few were thought to have been taken by collectors from the Smithsonian Institution in 1892 when an expedition found eight on Guadalupe Island after no recorded sighting for the preceding 8 years. Most of those found there that day were killed, but one survived due to increasing inclement weather that forced the expedition to abandon the site. A later study calculated through simulation analyses that there had been about 20 individuals left at the species nadir, and it further demonstrated the extent of lost diversity at various genetic markers (Hoelzel *et al.*, 1993, 2002).

Bonnell and Selander (1974) and later studies showed the potential impact of human exploitation on genetic diversity (though it was not until later that the direct impact was demonstrated through the comparison of samples before and after bottleneck events using ancient DNA; e.g., Groombridge *et al.*, 2000; Hoelzel *et al.*, 2002). The next question was, what difference does it make? Are species or populations depauperate of variation really at a disadvantage? Apart from the need to retain adaptive variation, there was the possibility that low diversity could affect individual fitness. In the early 1980s, a very influential study by Ralls and Ballou (1983) illustrated the impact of inbreeding depression (sexual recombination of deleterious alleles during consanguineous matings, exposing homozygous recessive traits) on a range of mammalian species based on data from zoological collections. However, the potential harm from inbreeding depression when close relatives mate had been recognized for some time. For example, Darwin compared self- and cross-fertilization among 57 species of plants and found that self-fertilization reduced seed production by 41% and plant height by 13% on average (Darwin, 1876). Even so, the paper by Ralls and Ballou (1983) inspired a search for evidence of inbreeding depression in “natural” populations, and there was ample evidence reviewed by Crnokrak and Roff (1999).

In the early 1980s, a number of papers illustrated the correlation between diversity at allozyme markers and various indicator measures of fitness. For example, Koehn and Shumway (1982) showed that the number of heterozygous loci correlated with O_2 uptake in the American oyster (*Crassostrea virginica*) per unit time, such that greater heterozygosity correlated with lower uptake of O_2 (greater efficiency). Around this time, the indirect measure of fitness based on fluctuating asymmetry (FA; van Valen, 1962) was also being assessed in this context, and a number of studies looked for correlations with genetic diversity. For example, Leary *et al.* (1983) assessed FA in the rainbow trout (*Oncorhynchus mykiss*) and showed that the number of asymmetric characters decreased with increasing number of heterozygous loci. To the extent that FA, the unbiased asymmetry of bilateral traits, reflects developmental stability (such that the expected symmetrical state has been disrupted), it could reflect the disruption of intergenic associations due to stochastic processes when populations are small and inbred. These and other measures could have reflected reduced fitness due to inbreeding, but the relative fitness of the heterozygote compared to the homozygote could also be a factor. The latter could come about by balancing selection, either through the advantage of the heterozygote,

spatial, or temporal variation in adaptive advantage or through frequency-dependent selection (well-established examples include resistance to sickle cell anemia and selection favoring diversity at immune system genes; e.g., Penn *et al.*, 2002).

Therefore, within a decade or so, a principle had been established that recognized threats to population size (and therefore to genetic diversity), together with a good foundation of work indicating a negative impact on fitness (and by implication species survival) due to the loss of genetic diversity. In this context, Franklin (1980) proposed the “50, 500 rule.” The “50” and “500” referred to effective population sizes (N_e ; an evolutionarily relevant measure of population size that represents the size of an idealized population that would show the same rate of decay of heterozygosity as the observed population). The essential idea was that an N_e of ~ 50 should be enough to avoid the short-term effects of inbreeding depression, whereas an N_e of ~ 500 would be required to avoid the long-term erosion of genetic variation in quantitative traits (phenotypic traits involving multiple genes) with high heritability. Franklin chose to consider quantitative traits because it is a phenotypic variation that is exposed to selection, and so this type of variation could allow a population to respond to a changing environment. The genetic variance at quantitative traits can be divided among “additive” and “nonadditive” components, but most quantifiable phenotypic variation will be determined by additive variance (V_A), a correlated effect seen at multiple genes, and so he focused on this aspect. In small populations, the rate of change in V_A should be determined by the rate of lost diversity through genetic drift and by the gain through mutation. Since the rate of loss in diversity is related to N_e , and at equilibrium (between genetic drift and mutation) the change in V_A becomes zero, an approximate value for a minimum N_e in this context could be calculated from data available at the time. This figure was $N_e=500$, though various higher and more recent estimates have been made (some as high as $N_e=5000$).

In the 1980s the 50, 500 rule was used quite extensively, especially by managers promoting the protection of populations under the US Endangered Species Act (ESA; enacted in 1973). Two quite high-profile occasions involved bird species in protected habitats. The northern spotted owl (*Strix occidentalis*) is found especially in old growth forest in western North America from California to Canada. In 1984, an estimated 2500 breeding pairs remained, and at that time the US Forest Service instituted a management plan based on the preservation of at least 500 pairs to maintain genetic diversity. This species was eventually listed as threatened in the states of California, Oregon, and Washington under the ESA in 1990. The red-cockaded woodpecker (*Picoides borealis*) lives in colonies in pinewood forests that are at least 80 years old. It was listed under the ESA in 1973 when there were an estimated 6000 birds. In 1985, the US Fish and Wildlife Service proposed a recovery plan under which a minimum of 500 birds would be retained to maintain genetic diversity. In each case, it was the number of individual birds that was to be managed (> 1000 for the owl and > 500 for the woodpecker), not N_e , which can be an order of magnitude or more smaller than the census number (see Low Diversity and Small Populations).

Largely in response to the use of this shorthand measure in the ongoing development of management policy (though not specifically in response to the mistaken focus on census number rather than N_e), Russ Lande published a highly influential paper in 1988 titled “Genetics and Demography in Biological Conservation,” in which he focused on a number of key points. First was the concern that a convenient metric (e.g., $N_e > 500$ to conserve genetic diversity) could lead to management plans that neglect essential factors, indicating the need for protecting a larger population. His focus was primarily on demographic factors such as Allee effects (when small populations experience low viability and reproduction for nongenetic reasons, such as difficulty in finding a mate, in addition to genetic reasons such as inbreeding), demographic stochasticity, edge effects, and local extinctions. The issue of N_e compared to the census size is again important here since an N_e of 500 could mean a census population size of 5000, 50,000, or more, and it is the census population size that is relevant to processes like demographic stochasticity. Lande made an example of both the northern spotted owl and the red-cockaded woodpecker. In the case of the former, he pointed out that models based on stochastic demography and habitat occupancy suggest a trajectory toward extinction if only 500 pairs were preserved due to the sparseness of the habitat. He cited habitat fragmentation as the particular problem with the red-cockaded woodpecker as well, and he predicted population decline under the proposed management plan. At the same time, if the managers working with the northern spotted owl, for example, had planned to preserve an N_e of 500 (perhaps 5000 birds) rather than a census number of 1000, this would have made a difference.

Another aspect of Lande’s argument was the suggestion that a gradual reduction in population size, which may often be the case, would result in relatively little inbreeding depression since selection would purge deleterious recessive alleles when they become homozygous. However, more recent studies suggest that purging is not a very efficient process and that low diversity does correlate to greater extinction risk (see Frankham, 2005; and see Low Diversity and Small Populations). Lande’s conclusion – that demography may be more important in assessing minimum viable population sizes than population genetics – formed the basis for a long discussion on the subject and raised questions for some at the time about the utility of conservation genetics. The idea that species are typically driven to extinction before genetic factors could have an impact (referred to as the “Lande effect”) is addressed in a meta-analysis by Spielman *et al.* (2004), which suggests that this is not the case.

However, the broader issue about the utility of conservation genetics has been addressed in other ways as well. As pointed out in the editorial of the first issue of the journal *Conservation Genetics*, the potential applications of genetic methods in support of more-effective conservation are diverse. Beyond the simple identification of levels of diversity or the estimation of effective population size, genetics can provide taxonomic identification (e.g., in support of wildlife forensics), assess introgression (e.g., between introduced and native species), identify management units for stock management (and the rate and direction of gene flow among stocks), assess behavior relevant to management (e.g., kinship and reproductive

behavior), track demographic histories, assist the practical management of captive populations, and aid in the assessment of local adaptation, among numerous other aspects. The remainder of this essay will focus on modern approaches to these various aspects and begin with our current understanding of the earlier question about the impact of lost diversity on everything from organismal health to species survival.

Low Diversity and Small Populations

The effect of genetic drift on diversity in small populations, confirmed in various laboratory and natural experiments, focused minds on the urgency associated with reduced population size. As Lande (1988) reminded us, conservation biology is a “crisis discipline” with negative impacts (especially anthropogenic impacts) mounting all the time. Although he was more concerned with the extinction of small populations for demographic reasons, there is growing evidence that the loss of genetic diversity also plays a crucial role (e.g., Spielman *et al.*, 2004). However, the loss of genetic diversity is related to the effective population size (N_e) in particular. Therefore, one of the most useful roles for conservation genetics in addressing this problem has been to provide methods for the estimation of N_e . At the same time, N_e is difficult to measure using genetics because of the stochastic nature of the key relevant processes (inbreeding and genetic drift) and the various factors that influence those processes (e.g., mutation, selection and migration).

Given full information about population demographic histories, reproductive behavior (especially sex-biased skew in reproductive success), variance in family size, and various other factors, it would be possible to calculate N_e without genetic methods, but these details are rarely fully known. Instead, genetic markers can be used to estimate current N_e if the “systemic” forces of mutation, migration, and selection can be ruled out. In that case, changes in allele frequency over time will be due to the stochastic process of genetic drift, and since there is a known relationship between genetic drift and N_e , N_e can be estimated. The systemic forces can be controlled for by making some basic assumptions. First, for estimates of current N_e we assume a closed population (and so no migration). We also assume a short time frame (so no mutation, since mutation is a very slow process) and base analysis on neutral markers (so no selection). The first assumption is often most problematic, but the implications of violating this assumption can be assessed and the results interpreted accordingly.

Two common methods for estimating current N_e are the “temporal method” and linkage disequilibrium (LD). The temporal method further assumes random mating and discrete generations (though some models allow overlapping generations), and it considers the change in allele frequencies between generations. Allele frequency changes will be due to genetic drift and sampling effects, so accounting for the latter allows for an estimate of the effects of genetic drift and therefore N_e . LD (a nonrandom association of alleles at different loci in gametes) can be generated in finite populations by migration, selection, and genetic drift (even without physical linkage on the chromosomes). Therefore, the same assumptions again allow us to focus on genetic drift and

estimate N_e . A rather different approach is to assume a state of equilibrium between mutation and genetic drift and estimate long-term, average effective population size. This is based essentially on a simple relationship between diversity (designated as θ) and N_e , such that $\theta = 4N_e\mu$, where μ is the mutation rate. A challenge is to estimate the mutation rate accurately.

In general, estimates have shown that N_e can be much smaller than the census population size, and this is important especially if the apparent census size is large (giving the appearance of a population not at risk). Although in a review Frankham (1995) suggested a typical value of about 10%, in some cases N_e can be several orders of magnitude smaller than N (common for pelagic marine fish species; see White *et al.*, 2011) or quite close to N (as in some natural populations of *Drosophila*; see Shapiro *et al.*, 2007). Some populations apparently have naturally low levels of N_e ; for example, Bourke *et al.* (2010) proposed that golden eagles in the British Isles have always had a low N_e despite once being more widely geographically distributed. A more extreme case would be naturally inbreeding populations, including selfing species of plants and some eusocial species such as some species of Hymenopteran insects (especially bees and ants). This raises the question of how such populations can survive the concomitant loss of diversity, especially the impact of inbreeding depression.

Because inbreeding exposes deleterious recessive alleles and expresses the associated phenotype, natural selection should purge them from the population with the loss or reduced fitness of those individuals. However, research into purging (which has largely focused on laboratory species such as *Drosophila*) suggests that the positive effects are variable and often small (see Boakes *et al.*, 2007). For example, Fox *et al.* (2008) performed serial inbreeding experiments (full-sibling mating over a few generations) in laboratory populations of a beetle (*Stator limbatus*). They found that the genetic load of recessive alleles was rapidly and efficiently purged but that despite this, 61.5% of the populations became extinct due to the stochastic fixation of deleterious alleles via genetic drift. Purging is likely to be more efficient in populations where alleles have a large deleterious effect (because selection quickly removes individuals expressing such alleles) when alleles are completely recessive (so they are not masking other deleterious alleles), when inbreeding is slow (so the population does not become extinct before purging can occur), when the population is large (so selection is more effective), when the population is naturally inbreeding (because long-term inbreeding will have reduced the genetic load), and where the population is sufficiently isolated such that immigration does not reintroduce purged deleterious mutations. For a review, see Charlesworth and Willis (2009).

Therefore, in spite of the potential for purging to reduce the risk of inbreeding, there remains strong evidence that low diversity and inbreeding constitute a significant conservation risk. For example, a meta-analysis of the effect of inbreeding depression on extinction risk in 30 mammal and bird species found that inbreeding depression decreases the time to extinction by an average of 37% (O'Grady *et al.*, 2006). Inbreeding depression has the potential to reduce any component of reproductive fitness, including birth weight, growth rate,

survival, parasite resistance, and tolerance to environmental stresses (Keller and Waller, 2002). It is also likely to be more severe in harsh and stressful environments; for example, Keller *et al.* (2002) found that inbreeding depression in Galapagos finches was five times more severe in years with low food availability and high population densities. As described earlier, factors such as frequency-dependent selection or heterozygote advantage are also important in some cases and best described for the evolution of immune system genes (e.g., Nei and Rooney, 2005). In this case, individual heterozygosity can itself be positively correlated to fitness.

Assessments of heterozygosity and fitness correlations (HFCs) have revealed variable results, although there is general agreement that genetic diversity does correlate positively with fitness (Chapman *et al.*, 2009). However, a correlation may be supported in several ways. There may be some direct association between the locus and fitness, as may have been the case for some of the allozyme studies showing HFCs, since diversity at these loci reflects function. It is also possible that there are relevant functional genes linked to the neutral markers under investigation. Perhaps more common, though, is the assumption that neutral markers will reflect the general diversity of the genome and so imply genomic diversity by inference. The extent to which this may be true is not yet fully known. In a meta-analysis by Reed and Frankham (2001), there was a weak correlation between molecular and quantitative measures of genetic variation but no significant relationship between genetic diversity and life-history traits. This could be because selection acts to maintain diversity at functionally important loci or conversely to purge deleterious alleles at those loci or because of the sometimes complex interactions among genes associated with phenotypic traits. For example, Olano-Marin *et al.* (2011) tested HFCs in blue tit populations using markers located at both neutral and functional loci. For neutral markers, they found a positive relationship between heterozygosity and fitness (measured as female hatching success and recruitment), but for markers located in functional genomic regions the relationship was negative. They attributed this to "outbreeding depression" at the functional genes. This can happen when local adaptation has generated complexes of genes that are not well-adapted elsewhere. In the blue tit study, there may have been a local effect such that diversity associated with these functional genes was negatively associated with fitness, whereas the neutral markers showed a positive correlation due to the effects of inbreeding.

In general, there are data in support of the perceived risks associated with small population size and lost diversity and therefore an interest in strategies for mitigation. This is often associated with controlling patterns of connectivity. For example, populations of conservation concern are often found in highly fragmented habitats. Small habitat fragments may only support a relatively small population; depending on the species and nature of the habitat, fragmentation may inhibit gene flow. The usual mitigation policy involves either the establishment of corridors among fragments or the translocation of individuals. The former may be more likely to succeed since differentiation between neighboring populations may be relatively low (avoiding outbreeding depression). Translocations need to be carefully managed with respect to levels of

Figure 1 A “skyline plot” showing how coalescent intervals from a genealogy can be used to estimate changes in effective population size over time. The number of lineages represented at each coalescent interval is given as k . Reproduced from illustrations in Pybus OG, Rambaut A, and Harvey PH (2000) An integrated framework for the inference of viral population history from reconstructed genealogies. *Genetics* 155: 1429–1437.

differentiation (or adaptation to a captive environment if relevant). The idea is to “rescue” genetic diversity. Laboratory studies of genetic rescue in inbred *Drosophila* lines found that the short-term rescued populations increased in fitness, but that this effect may break down after a number of generations, especially if the N_e of the population remains low (Bijlsma *et al.*, 2010). Genetic rescue has been practiced in managed populations with mixed results. For example, cross-lineage breeding between captive Mexican wolves (an endangered subspecies of the gray wolf) increased fitness (measured by an increase in offspring number) in cross-lineage wolves (Hedrick and Fredrickson, 2010). However, for the Scandinavian wolf, genetic rescue resulted in an initial increase in fitness but then an increase of inbreeding depression in subsequent generations (Liberg *et al.*, 2005).

Another important consideration is the demographic trajectory of populations, and genetic methods can help to assess these trends as well. Wright (1931) noted that the probability that two gene copies come from the same gene copy in the previous generation is $1/2N_e$, so every generation there is a $1/2N_e$ chance of coalescence (the lineage coming together as you look backward in time). John Kingman later generalized this idea to consider multiple gene copies and showed that the interval between coalescent points is related to N_e (see Kingman, 2000), and so changes in N_e over time can be estimated based on gene genealogies. This method of tracking the changes in N_e was initially referred to as a “skyline plot” (Figure 1; Pybus *et al.*, 2000), and it has since been developed into quite a powerful tool that can track demography even over relatively short timescales, given the application of multiple genetic markers (see Ho and Shapiro, 2011 for a review). The method is greatly enhanced when data from ancient DNA are incorporated, providing a fuller representation of historical coalescent points.

Therefore genetic methods can facilitate conservation through the identification of populations that have small effective sizes by tracking the dynamics of populations – for example, by allowing mitigation for populations in decline – and by quantifying the impact of low diversity and the potential contribution that may have on extinction risk. This has been a central component of the growing field of conservation genetics since its inception. However, in recent years the dominant body of work has instead been on the next step up in the hierarchical structure of diversity: differentiation among populations.

Population Structure

The initial variation documented by allozyme studies at the population level was already a revelation, but the full details were appreciated only after DNA sequencing data became available. For example, Kreitman (1983) sequenced part of the alcohol dehydrogenase (ADH) locus in five natural *Drosophila melanogaster* populations and revealed 42 silent (i.e., no amino acid change) polymorphisms. A well-known two-allele allozyme system (comprising a “fast” and a “slow” allele) was thereby shown to reflect considerable neutral variation as well, and the importance of variation among populations has since become increasingly apparent. Species are subdivided into populations connected to one another to a greater or lesser degree by gene flow and differentiated by the processes of genetic drift and natural selection. This means that the preservation of the potential to evolve (retaining diversity as the raw material for evolution) entails conserving diversity both within and among populations. A rapidly expanding human population and increasing habitat degradation complicates this objective since these activities lead to populations becoming further subdivided and isolated (a process of “fragmentation”). In addition, natural population structure can be cryptic (e.g., without obvious barriers to gene flow between them) representing diversity that may be important as populations adapt to changing environments over time but may not be intuitive from the physical structure of the environment. As a consequence of these and related factors, quantifying the level and patterns of differentiation between natural populations has become a major focus of conservation genetics.

Genetically differentiated populations can evolve in isolation (“allopatry”), and this is the most obvious and easy to predict pattern of population structure. There can also be differentiation in sympatry (same geographic range) or parapatry (populations next to each other), though examples are less common and more controversial. Populations often show a pattern of isolation by distance (increasingly differentiated with greater geographic distance), though not always, and isolation by distance may also reflect a continuous pattern, not subdivided into populations. A useful definition of a *population* toward more effective conservation needs to incorporate the evolutionary forces of gene flow, mutation, drift, and selection. A commonly used definition is “a group of individuals living in sufficiently close proximity that any member of the group can potentially reproduce with any other member” (Waples and Gaggiotti, 2006). Such groups are “panmictic”

(free flowing) with respect to gene flow within the group, separate from other similar groups, and distinct from an “ideal” population (see Beginnings).

Highly variable genetic markers are now readily available for essentially any nonmodel organism, and increasingly easy and inexpensive to screen (e.g., see [Pearse and Crandall, 2004](#)). In practice, there are two main approaches for identifying genetically distinct populations. The first is based on determining the degree of genetic differentiation between predefined putative populations (the statistical rejection of panmixia). By this method, putative populations are identified a priori based on factors such as geographic isolation or apparent barriers to gene flow. The second is based on using information from multi-allelic markers to cluster individuals into groups by some methods without a priori assumptions about putative population boundaries. Investigating population structure using the first approach has been largely based on F -statistics (or a derivative of F -statistics), which are “fixation indices” that describe the partitioning of diversity in a structured population at different hierarchical levels (e.g., for the individual within a subpopulation, as F_{IS} , the inbreeding coefficient, and for subpopulations in the total population as F_{ST} ; [Wright, 1931](#)). Population structure can be assessed using F_{ST} , which quantifies differentiation among populations (expressed as a value between 0 and 1, where 0 implies panmixia and 1 implies no gene flow). Although the magnitude of F_{ST} has some meaning, the primary initial question is typically about whether or not panmixia can be rejected (whether or not F_{ST} is significantly greater than zero). [Wright's \(1943\)](#) original “island” model considered a complete set of subpopulations, however it is as common to see pairwise population comparisons as a single measure considering the structuring of all sampled populations, and the inference about significant structure remains valid.

In some cases, the apparent level of structure will be small and the interpretation in the context of conservation strategy somewhat equivocal. For example, a study on population structure in sockeye salmon sampled from 11 different spawning sites and applied the criteria that a gene-flow rate between populations of less than 10% would be enough to render the populations independent. Because the N_e of each population was estimated to be approximately 1000, it was estimated that there would be panmixia if F_{ST} was below 0.0025 (thus reflecting gene-flow rates of less than 10%). However, F_{ST} was calculated to be 0.007, suggesting that even though differentiation was very low it was strong enough to reject panmixia and warrant the separate management of the 11 spawning-site populations ([Ramstad et al., 2004](#)). At the extreme there is some question about the meaning of these very low values of F_{ST} , a question addressed directly in a study that combined population genetic assessment with an extensive capture–mark–recapture study of Norwegian cod (*Gadus morhua*; [Knutson et al., 2011](#)). The authors concluded that although the F_{ST} values were very low (average was 0.0037), they were nevertheless consistent (over 10-year replicate samples and among loci) and supported by the mark–recapture data, where individuals were most likely to be recaptured near their initial site of capture. For this example at least, the small but significant measure of genetic structure did appear to provide useful inference toward effective conservation and

management. More generally, the “rejection of panmixia” method has been criticized by some because low rates of gene flow (theoretically just one migrant per generation, though usually more than this in real populations) can be enough to prevent divergence, and conversely populations may be demographically independent even when gene flow is high (see [Palsboll et al., 2007](#)). [White et al. \(2011\)](#) modeled the latter question and showed that sufficient migration to make demographic trends match among populations may be too high to be detectable using genetic methods.

The “individual assignment” approach can also be based on the initial identification of putative populations, in which case the relative likelihood of assignment to sample site compared to alternative populations is assessed based on individual genotype profiles and the distribution of allele frequencies in each putative population. However, assignment to populations does not require populations to be predefined and can instead use information contained within multi-allelic markers to cluster individuals into populations based on either minimizing deviation from equilibrium assumptions (concerning the equilibrium between migration and genetic drift) or grouping populations based on similar allele frequencies (using one of several “principle components” clustering analyses). These methods are especially useful for populations that are difficult to define a priori (especially when individuals have a continuous geographic distribution) or when there is cryptic population structure between sympatric populations. For example, the European gray wolf is a highly mobile animal, with a relatively continuous distribution and no obvious geographic barriers to gene flow. However, investigation of the population structure in Eastern Europe using neutral microsatellites found two distinct population clusters, suggesting restricted gene flow and cryptic population structure ([Pilot et al., 2006](#); [Figure 2](#)) and implying an important change in conservation strategy for this species. Clustering approaches that quantify the degree of assignment can also allow estimates of the degree of admixture (historical gene flow between different populations), which can help with the determination of the history and extent of isolation.

Conservation managers are interested in the practical utility of population structure for defining the population segments that require management (coined *management units*, or MU, by [Moritz, 1994](#)). Although the exact definition of an MU varies (and has been refined over the years, see below), the idea is that genetically distinct populations should be managed separately to preserve locally adapted population genetic variation and independent evolutionary processes. A deeper level of divergence was defined as an *evolutionarily significant unit* (ESU) and contrasted with an MU by Moritz in his 1994 paper. The general idea has been officially recognized at the policy level for some time in the US as *distinct population segments* under the ESA, which are afforded similar protection as species. However, the application of DPSs has not been without controversy. One famous example is that of the red wolf. The red wolf was once widely distributed across the southern US, but hybridization with coyotes was thought to have resulted in the loss of almost all pure red wolf individuals. Consequently, the red wolf was afforded protection under the ESA. However, later genetic analyses suggested that

Figure 2 Assignment of individual wolves to subpopulations identified from microsatellite DNA clustering analyses. Note that distinct populations were identified despite the continuous range of wolves (dark gray area) in the region.

the red wolf was formed as a hybrid between the gray wolf and the coyote (neither of which were listed as endangered; Wayne and Jenks, 1991; Reich *et al.*, 1999), and the protection status of the red wolf was subsequently hotly disputed (see Allendorf *et al.*, 2001).

The routine assessment of MUs has been common, exemplified by fisheries management. For example, it is recognized that many salmon fisheries are comprised of different population units that have either been historically isolated or have functionally significant adaptive differences. Consequently, the need to define and manage such populations as separate stocks has been effectively applied in salmon fisheries across the globe (e.g., Beacham *et al.*, 2004). Later revisions to the concept of an MU have included the suggestion that adaptive variation and ecological specialization are more important than genetic differentiation at neutral markers (Crandall *et al.*, 2000). The debate about the relative importance of historical isolation (reflected in neutral markers) compared to functional differences is likely to be resolved eventually by our increasing ability to address both (see below) but can also be addressed in part by protecting distinct populations across a range of different habitats, thus preserving both past evolutionary processes and selective pressures (Moritz, 2002).

An essential aspect of understanding population structure is the further understanding of the pattern of connectivity among populations. Fixation indices and clustering methods allow us to understand population structure in terms of

population differentiation (which is a function of gene flow), but we can also use genetics to specifically quantify the level and direction of gene flow among populations. Traditional population genetic methods for estimating gene flow used Wright's island model to calculate the effective number of genetic migrants per generation (Nm). Because of a simple relationship with F_{ST} , Nm is relatively straightforward to calculate. However, Wright's island model makes some simplifying assumptions that may not be biologically realistic (such as equilibrium between migration and genetic drift, equal subpopulation sizes, equal migration rates between subpopulations, no mutation, and no selection), and it only gives us an estimate of the magnitude of gene flow between subpopulations, providing no information about the directionality (Whitlock and Macaulay, 1999).

With increasingly powerful computers, we can now estimate migration rates much more effectively using modeling approaches based on coalescent theory (see above) to provide us with estimates of asymmetrical migration rates between subpopulations (directional gene flow). The basic principle is as follows. The coalescent models a gene genealogy for a population and works backward in time to find points on the genealogy where lineages come together (coalesce) and share a common ancestor. Separate populations, reflecting different lineages, reveal directional gene flow when the historical coalescent for an individual is in a population different from the one it was sampled in (Figure 3). The specific approach used depends on whether (1) the subject

Figure 3 Illustration of an individual belonging to one lineage found in a population dominated by another lineage to show how coalescent analysis can provide information on directional migration (in this case, from population A to population B).

populations diverged from one another a long time ago such that they exchange migrants at a constant rate over evolutionary time (Beerli and Felsenstein, 2001) or (2) they diverged more recently and are still exchanging migrants with one another at a variable rate (Hey and Nielsen, 2004). Both methods have been applied successfully to determine directional migration rates, but the second class of methods is especially useful for looking at more recent patterns of gene flow. These latter methods employ an isolation with migration (IM) model, which assumed that two populations (N_1 and N_2) have diverged from a single ancestral population (N_A) at some time point (t) in the past (though note that more recent versions allow for multiple populations; Hey, 2010). Hoelzel *et al.* (2007) used the IM model to determine that ongoing low-level gene flow was occurring between distinct populations of killer whales (*Orcinus orca*) despite there being considerable population structure and different resource specializations suggesting possible isolation. This type of inference is important as it indicates the need for continuing to facilitate connectivity, even when populations appear to be strongly differentiated. Although methods that assume divergence a long time ago also assume an equilibrium between genetic drift and migration, IM is in this sense a “nonequilibrium” model, since it simultaneously estimates a point of divergence and the migration rate after that point in time (although it is an average rate following the time of divergence).

Contemporary dispersal between populations can also be estimated using assignment tests, though the relevant time frame is very short and may not reflect gene flow (unless historical admixture is being assessed). One complication is that migrant individuals are easier to detect when there is strong population structure (and hence different allele frequencies between populations), but strongly differentiated populations will not be exchanging many migrants. Conversely, migrants are difficult to detect when population structure is weak, despite migration occurring at a higher rate. Using genetics to assess contemporary population assignment is especially useful in the fight against wildlife crime – wildlife forensics. Before the widespread use of genetic methods it would be extremely difficult to identify the origin of products in trade or to determine whether specimens had been poached illegally. Genetic assignment tests can identify biological samples to species and in some cases populations. For example, Wasser *et al.* (2008) used assignment tests to determine that a large volume of elephant ivory traded in Asia and Africa originated from a common geographic area, suggesting that

elephant populations in some regions were being hit particularly hard by ivory poaching.

Another factor with potential relevance to conservation is the possibility of sex bias in gene flow, in which one sex may disperse further or more frequently than the other (for a review see Lawson-Handley and Perrin, 2007). This can be assessed either by comparing biparentally inherited autosomal markers between the sexes (whereby postdispersal individuals of the dispersing sex should show weaker population assignment and population structure) or by using markers with sex-specific modes of inheritance, notably mitochondrial DNA or the W chromosome (for species like birds with a ZZ/ZW sex determination system) in females and the Y chromosome in males. For example, Kerth *et al.* (2002) investigated population structure in the Bechstein’s bat using both autosomal and mitochondrial markers and found mitochondrial differentiation to be more than 60 times higher than autosomal differentiation, suggesting female philopatry and male-biased dispersal in this species.

Describing the structure of populations is useful one species at a time, but broader inference requires an appreciation of the underlying mechanisms. One approach to learning more about this is to consider how geographic and environmental variables may have differentially affected gene flow across a landscape (for a review, see Segelbacher *et al.*, 2010). Most such landscape genetic studies have two key steps: first to identify genetic discontinuities, and second to correlate these discontinuities with landscape and environmental features. Methods that identify discontinuities have generally focused on global statistics that identify large-scale patterns within a landscape. These include matrix correlations such as Mantel tests, which test for a significant statistical association between genetic and geographic distance (isolation by distance); spatial autocorrelation analyses, which test whether individuals adjacent in space are more genetically similar than those farther apart; and clustering methods, which use genetic and spatial information to group individuals into populations. In the second step, local landscape or environmental features that may act as barriers to gene flow are assessed. Various methods have been applied but typically are individual-based analyses (like assignment tests), which makes them well-suited to investigating fine scale processes. For example, Perez-Espona *et al.* (2008) used least-cost analyses to investigate the impact of landscape features on gene flow in red deer populations in the Scottish highlands. They found that landscape features significantly affected gene flow (sea lochs, slopes, roads, and forests acted as barriers whereas inland lochs and rivers promoted gene flow), explaining more of the variation than geographic distance alone. Essential components of these analyses are an accurate assessment of environmental variables and an appropriate choice of geographic scale for the focal species.

Population structure also has a temporal dimension, which may reflect historical processes or events. A common approach to investigating this has been “phylogeography,” a method described in detail by its main proponent, John Avise, in his book of the same title (Avise, 2000). Phylogenies based on samples from populations distributed across a geographic range (often constructed from mtDNA sequences) are interpreted in the context of both geography and lineage history.

One system about which considerable insight was revealed from this approach was the dynamic population structure of various species during and since the last glacial maximum in Europe. The ice age forced species to relocate further south into three principal areas of refuge – Anatolia, Italy, and the Iberian peninsula. The signature of this period of isolation and patterns of mixing to various extents following the retreat of the ice and during migrations north were evident in the phylogenetic reconstructions. These processes have played an important role in the structuring of natural populations in Europe (see review in [Hewitt, 2000](#)). More recently, population dynamics and historical connectivity have been investigated using methods based on the coalescent and simulation modeling, providing even greater insight into the processes that have shaped population structure (see review in [deBruyn et al., 2011](#)).

Investigating population structure using neutral markers has provided a wealth of information on demographic processes associated with genetic drift (especially related to gene flow and population size). These data on connectivity, population history, and the rate and direction of gene flow are central to the development of effective conservation strategies. However, the potential for local adaptation is also of conservation concern. Neutral markers are only informative about natural selection when linked to a functional gene. For example, [White et al. \(2010\)](#) investigated population structure in a deep sea fish (*Coryphaenoides rupestris*) in the North Atlantic and found significant population structure only at a locus that showed deviation from neutral expectations. Allele frequencies at this locus were strongly correlated with the depth at which the fish had been living, suggesting linkage to a functional gene associated with adaptation to depth. However, phenotypic traits often involve multiple genes; some effects may be associated with the control of other genes in the system, and the key differences in different environments may relate to gene expression rather than allelic variation. Therefore, although examples of linkage to neutral markers suggesting local adaptation exist, this is not a very reliable way to detect selection at functional genes.

Given a “candidate” gene that may be under selection, various tests can be applied to look for relevant signals. Selection acts on phenotypes and genotypes, and it can increase the frequency of a favorable allele (or decrease the frequency of an unfavorable one) through “directional” selection. It can also favor diversity by frequency-dependent selection on different alleles, spatial or temporal patterning to selection, or selection for heterozygous genotypes (“balancing” selection). Selection therefore affects allele frequencies, and so methods that detect departures from a neutral distribution of alleles can be used to detect selection, though departures from neutrality may also be due to demographic effects (e.g., [Tajima, 1989](#)). Another potential signature of selection can be assessed by investigating the pattern of change in codons (the three-base code that determines the amino acid sequence in a protein) within coding genes. Only some base pair changes result in a change of amino acid (“nonsynonymous” changes), whereas the rest are silent (“synonymous changes”). Because the rate of nonsynonymous substitution under neutrality is expected to be equal to the mutation rate, the ratio of nonsynonymous to synonymous change (d_N/d_S) should be 1. Under negative directional

selection, d_N/d_S will be less than 1, whereas under positive directional selection and under balancing selection it should be greater than 1 (see [Nielsen, 2005](#)). Screens of many genes at once have identified outliers as anonymous, possible candidates for being under selection, though this approach is controversial.

Another possibility is to screen genes at the population level and test the expectation that there should be a predictable relationship between diversity within populations and genetic differentiation between them (typically assessed using F_{ST}). If there is more differentiation than expected for a given level of diversity, then this suggests directional selection, whereas lower suggests balancing selection (see [Foll and Gaggiotti, 2008](#)). For example, the marine snail species *Littorina saxatilis* has two divergent ecotypes found in different rocky shore habitats, and there are phenotypic differences between the ecotypes. [Galindo et al. \(2009\)](#) compared multiple loci from across the genome to identify outlier loci associated with ecotype differences, and they compared population structure using outliers versus selectively neutral loci. They found population structure to be far stronger using the outliers, which suggested that selection was promoting divergence between the ecotypes despite ongoing gene flow.

One set of genes stands out as having special conservation relevance, and those are the genes involved in immune response. There is ample evidence that diversity is selected for at these loci, in response to pressure from the diversity of environmental pathogens (e.g., [Klein, 1987](#)), and this extends over a broad range of studies involving natural populations (see [Bernatchez and Landry, 2003](#)). There was some initial enthusiasm for a focus on these genes in particular in support of conservation (e.g., [Schreiber and Tichy, 1992](#)), though also the realization that this is only one aspect of a more complicated storey (e.g., [Miller and Hedrick, 1991](#)).

Assessing the patterns of genetic structure at neutral and selected loci in natural populations allows us to determine best strategies for conserving the natural state and to understand the processes that generate the observed patterns of structure and connectivity. However, another key objective is to help address problems that we generate as we exploit the natural world and construct roads and cities around it. Habitat fragmentation and degradation are particular concerns, because the consequent reduction in gene flow can result in increasingly isolated populations and the loss of genetic diversity (and therefore evolutionary potential) through genetic drift and inbreeding (see [Beginnings](#)). For example, [Reed et al. \(2009\)](#) compared historic and contemporary levels of gene flow between nine populations of a wolf spider (a species that disperses by a form of wind-driven dispersal called “ballooning”). Historically, they found that gene flow between populations occurred at a rate of 1.5 migrants per generation but that this dropped to 0.2 migrants per generation in extant populations. The dramatic decline in gene flow coincided with an increase in habitat fragmentation in the area in which the spiders were sampled, suggesting that anthropogenically mediated habitat degradation was having a negative impact. However, some studies have found habitat fragmentation to have no effect or even to increase gene flow in some circumstances, likely a consequence of differences in life history. In a review on the genetic effects of fragmentation in plants, [Young et al. \(1999\)](#) found that factors such as longevity, pollination system, and mating system all

had the potential to influence whether or not a population was adversely affected by fragmentation.

Human disturbance can also work the opposite way and force hybridizations (the interbreeding of individuals from genetically distinct populations or species) that are maladaptive (see Allendorf *et al.*, 2001). One well-known example is that of the white-headed duck, a globally threatened species that has been negatively affected by hybridization with the invasive ruddy duck. Using genetic markers, Munoz-Fuentes *et al.* (2007) were able to show that the hybridization process had begun in the last pure stronghold of the ruddy duck in Europe, but there was no evidence for widespread introgression (incorporation of foreign genes), suggesting that conservation measures could be implemented in time to save this population. Both of these examples of the potential impact of human influence show how understanding more about the behavior of individual organisms can be valuable toward the development of more-effective conservation strategies.

Individual Genotypes

In the previous sections (*see* Beginnings, Low Diversity and Small Populations, and Population Structure), we describe how individual fitness is correlated with genetic diversity, how genotypes can facilitate individual assignment to populations, and how this can facilitate wildlife forensic investigations. Here we consider how knowing individual genotypes can provide information on behavior or inform about processes that can influence the level and distribution of diversity within populations relevant to the development of effective conservation strategies. For example, populations may show genetic substructuring around kin groups, or a skew in reproductive success may affect levels of diversity. Dispersal behavior that shows a directional or sex bias may provide important information about population trends or habitat requirements, and food resource requirements can be assessed through the molecular identification of food species.

The identification of kin relationships is important due to the possible clustering of kin (e.g., in social groups) and because reproductive skew reduces effective population size. The most straightforward application is the identification of parent–offspring relationships. This involves subtracting the genotype of one diploid parent from the profile of the offspring in order to identify the other parent, though it is necessary to have a sufficient number of polymorphic loci to reduce the probability of chance identifications, and it is often necessary to compensate for possible genotyping errors (see Queller and Goodnight, 1989). Although parentage can sometimes be estimated by observing mating events between individuals, there are obvious limitations and logistical considerations (e.g., if there is a poor correlation between association and mating success, failed fertilization). For species such as mammals, where there is a dependent association between mother and offspring, the identification of the mother–offspring pair can serve as the basis for the identification of paternity.

The apparent extent of skew can sometimes be very much at odds with the reality. For example, the reed bunting is a monogamous bird in which parental care is shared by the

sexes; however genetic paternity tests revealed that up to 55% of chicks were sired as the result of extra pair fertilizations (EPF; Dixon *et al.*, 1994). That EPFs occur under monogamy is likely to be the rule rather than the exception, though the extent of EPFs and any consequent skew will vary among populations and species (Hughes, 1998). In addition, for some species in which reproductive skew was thought to be the norm, genetics has revealed that a significant portion of paternity can be assigned to sneaky copulations with subordinate or outsider males. Arguably the most extreme polygyny is displayed by the elephant seal. Single males can defend groups of hundreds of females in harems at annual breeding colonies. The males are several times as massive as the females and fight exhaustively with competing males for access. For the northern elephant seal, paternity testing indicated that some males showed a surprisingly poor correspondence between apparent success (based on observational behavioral data) and their lower actual success based on paternity testing (Hoelzel *et al.*, 1999). For this species, it is possible that severe depletion by overhunting is in part to blame, as genetic diversity was largely lost (Bonnell and Selander, 1974), and in other species this has been shown to affect reproductive health (e.g., Wildt *et al.*, 1987). At the same time, work with the southern elephant seal (*Mirounga leonina*) suggests that alpha male success may also be related to environment. Harem holders at the Falkland Islands where the tidal range is small were more successful than in Argentina where the tidal cycle is large, possible due to the greater access a large tidal range avails peripheral males as estrous females leave the beach (Fabiani *et al.*, 2004). These differences matter toward effective conservation, since skew can affect the relationship between apparent abundance and the effective population size.

Genetics can also be used to determine kinship beyond parentage based on shared alleles that are identical by descent (IBD) as measured by the coefficient of relatedness (r). For example, in a sexually reproducing diploid species, we would expect parents and offspring or full siblings to have an $r=0.5$, half siblings or cousins 0.25, and so on. However, based on genetic markers, unless the number of markers used is very large, these estimates provide a broad distribution of values around the expected mean and so provide approximate kinship with decreasing accuracy as the level of kinship diminishes. Expectations that social groups represent associated kin are sometimes shown to be correct (e.g., African elephants, *Loxodonta africana*; Wittemyer *et al.*, 2009) and sometimes not, even when social structure is very similar (e.g., sperm whales, *Physeter macrocephalus*; Ortega-Ortiz *et al.*, 2011). Each of these species shows a hierarchical social structure where the primary association is between mother and dependent calf, followed by stable female–subadult groupings, and then temporary associations of the stable groups. However, although the stable “level 2” elephant groups show average kinship at about the “cousin” level, this is more variable for the sperm whale, and average kinship among whales did not differ within compared to between groups.

Dispersal behavior is the primary driver of population connectivity and inbreeding, and it can be determined in part by social or mating behavior. For example, a mating system such as promiscuity fosters outbreeding, and in some species it

may have evolved as a mechanism to avoid mating with kin. In a harem or hierarchical system in which only a few males breed, daughters may need to disperse to avoid inbreeding. Although purging deleterious recessives is possible (*see* Low Diversity and Small Populations), inbreeding avoidance is a powerful force. One striking example involves killer whales: both males and females are known to remain in some social groups for life. This leads to fixed mtDNA lineages within regional groups and high levels of kinship within social groups. However, Pilot *et al.* (2010) found that male-mediated gene flow was occurring during temporary associations among social groups, including among social groups whose core home ranges were quite distinct. In this way, outcrossing was being promoted even without dispersal.

Mechanisms for inbreeding avoidance in plants reflect the complexity of their breeding systems, where self-fertilization is in some cases common. Some plants are obligate outcrossers because they possess self-incompatible (S) alleles preventing self-fertilization or that from a plant with a similar S-allele genotype. However, although this promotes diversity, it can limit productivity, especially in small, isolated populations when the diversity of S alleles becomes low. The various implications of plant breeding systems in the context of conservation strategy are reviewed by Barrett (2003).

The timing, direction and any sex bias associated with dispersal can also be assessed using individual genetic profiles in much the same way that this is done with tags or natural markings. Methods for estimating the extent and direction of gene flow based on population parameters were addressed in the previous section, but in some cases it is useful to use the permanent, unique nature of genetic identity to supplement those data by tracking individuals (or their propagules). For example, Riley *et al.* (2006) used a combination of radio tracking and genetic assignment tests (*see* Population Structure) to determine that freeways acted as significant barriers to dispersal for the bobcat and coyote, despite these species possessing strong dispersal abilities. In a study investigating sex-biased dispersal behavior, observational evidence suggested that both male and female bottlenose dolphins in southeastern Australia were philopatric. However, genetic assignment tests revealed that females were correctly assigned to their natal population more often than males (Moller and Beheregaray, 2004), suggesting male-biased dispersal.

Finally, individual genotypes can be used as a tool to help understand aspects of animal ecology (and habitat requirements), for example with respect to foraging behavior. This is most commonly based on genetic analyses to determine the dietary content of stomachs or scats. For example, little information was known about the dietary ecology of the Barbastelle bat due to its nocturnal habits and the degradation of soft prey tissues during digestion. However, Zeale *et al.* (2011) used DNA barcoding to identify 37 different taxa in scats, revealing broad resource requirements. For a review of molecular dietary analysis, see Symondson (2002).

Ex Situ Conservation

Sometimes habitats become so degraded or a species so rare in the wild that it becomes necessary to implement

ex-situ conservation measures. Ex-situ measures entail the captive breeding of organisms, often with a view to one day reintroducing their descendants into the wild. There are two primary objective that should be met during these efforts: first to retain as much of the natural diversity as possible, and second to avoid adaptation to the captive environment (at the expense of fitness in the wild). Various methods are employed to minimize inbreeding (and thereby maximize N_e), including equalizing family size and establishing pedigrees so that matings can be arranged that minimize kinship for the mating pair. Genetic methods can help both through the choice of initial founders and in the establishment of mating programs when pedigree data are not available.

A key challenge has often been the nature and size of the initial founder group. Especially for endangered species, there may be little option about which individuals are chosen to establish the breeding population. Genetic assessment of kinship can help early on so that the least-related pairs are bred (though the resolution is limited, *see* Individual Genotypes). Leaving them to their own devices can lead to substantial skew. For example, the golden lion tamarin (*Leontopithecus rosalia*) captive population was founded from 48 individuals and increased in size to 500, but pedigree analyses revealed that almost two-thirds of genes in the population had descended from a single breeding pair, revealing a need for managed breeding to reduce inbreeding (Ballou and Lacy, 1995). Subsequent managed breeding to minimize kinship between mated pairs greatly reduced the level of inbreeding for the golden lion tamarins.

Another concern is the sampling effect that occurs when the founder group is chosen (or during the bottleneck that reduced the size of the native population), potentially distorting allele frequencies. In this way, a rare recessive trait could become quite common in the captive population just by chance. A well-known example is the California condor (*Gymnogyps californianus*), which declined dramatically in the wild to a population of just 14 individuals. All individuals were brought into captivity and entered into a breeding program. The breeding program was a success, and numbers recovered sufficiently to begin reintroducing birds to the wild. However, managers noticed that a few chicks had begun to hatch with lethal deformities. Further investigation revealed the deformities to be consistent with chondrodystrophy – a form of dwarfism with an autosomal recessive genetic basis in the condor (Ralls *et al.*, 2000). Worryingly, the frequency of this recessive allele in the captive population was estimated to be ~9% – probably a consequence of the initial founder effect. Selective breeding can be used to reduce the frequency of the deleterious allele in the captive population, though as in this case, such a strategy has to be balanced against the risks associated with removing too many individuals from the breeding pool.

To avoid inbreeding and to minimize sampling effects, large founder sizes and large N_e in captive populations are key objectives. However, selection is a stronger force when N_e is large. Therefore, since adaptation to the captive environment has the potential to reduce fitness for organisms subsequently released into the wild, an intermediate effective population size may be most appropriate in captivity

(see Frankham, 2008). Araki *et al.* (2007) compared lifetime reproductive success of steelhead trout bred in captivity and released into the wild over three generations. They found that reproductive success declined by ~40% each generation for individuals from domestic stock, a process they attributed to the absence of selective pressures in captivity relevant to natural conditions. This has now been documented in a wide range of taxa, including plants, birds, amphibians, and insects (Frankham, 2008). Estimates of N_e using genetic markers may help breeders maintain an optimal captive population size. Experimental studies on populations of *Drosophila* (Morgan *et al.*, 1998) compared the efficacy of a single large effective population to several smaller subpopulations for maintaining diversity and reducing adaptation to captivity. They found that the smaller populations collectively had higher diversity, higher reproductive potential, higher fitness under competitive conditions, and lower inbreeding coefficients than the equivalent effective size managed as a single larger population. Although this strategy has yet to be tested on a large scale in captive populations of conservation concern, such experimental studies suggest it may be a viable management option (Frankham, 2008).

More generally, it is important to assess the compatibility between the organisms to be reintroduced (or translocated) and the proposed destination population. Apart from concerns associated with habitat suitability, genetic compatibility is important to avoid outbreeding depression (a reduction in fitness when individuals with divergent adaptive or genomic characteristics interbreed). Sagvik *et al.* (2005) tested the effect of outbreeding depression on the common frog by crossing individuals from two different populations (one from a large pond and the other from a small, isolated pond). They found reduced body size and increased deformities in F_1 tadpoles produced by crosses between females from the large and males from the small pond. The genetic component leading to reduced fitness may or may not be reflected in diversity at neutral markers, and ultimately it would be ideal to be able to investigate relevant functional gene systems directly. However, gross chromosomal compatibility can be assessed (e.g., with respect to chromosome number) and combining populations that are strongly divergent at nuclear markers can be avoided. For example, Pierny *et al.* (2005) assessed mitochondrial sequence variation among water vole populations in the UK and found divergent lineages between Scottish and English and Welsh regions, and consequently recommended against translocation among these sites.

For the longer term, cryopreservation of animal gametes and seed banks can help preserve diversity and permit a controlled management of diversity and reintroductions based on individuals of known genotype. These collections have the potential to be substantial, given the reduced space requirements and ability to store materials in a suspended state (dormant seeds or cryopreserved eggs and sperm). For example, the Millennium seed bank project at Kew Gardens, London, currently houses seeds from 10% of the world's wild plant species and aims to increase this figure to 25% by the year 2020. This will provide a valuable resource for promoting plant genetic diversity in the future, which is clearly important given the current rates of habitat destruction and climate change.

The Future

Substantial inference has been gained toward the more effective conservation of biodiversity based on the assessment of neutral genetic diversity (or diversity that was assumed to be neutral), greatly facilitated by advancing technologies for the more-efficient analysis of molecular markers. Allozymes reflected partial information because only coding regions were assessed and only some DNA changes were reflected in the different allozyme charge properties that could be detected as different alleles. "Chain-termination" sequencing allowed all base pairs to be analyzed for a given locus, but sequencing large regions by this method was time consuming. Something of a revolution in resolution was achieved through the analysis of repetitive DNA regions, which evolve by evolutionary processes (especially "DNA slippage") that are faster than point mutational change altering DNA sequence. These markers are also relatively easy to analyze, and "microsatellite DNA" loci especially remain widely used.

However, a new era began once the first entire human nuclear genome was sequenced (Venter *et al.*, 2001) based on traditional sequencing technology, and both the potential of having these data and the great expense and difficulty of generating it by existing technologies became evident (the Human Genome Project cost billions of dollars and took 10 years to complete). The new objective became the analysis of diversity across the genome, and at first this was facilitated by methods that looked at random loci defined by largely uncharacterized variation (amplified fragment length polymorphisms, or AFLP) and then by the more precise assessment of single nucleotide polymorphisms (SNP). Screening hundreds or thousands of SNP markers (e.g., using "microarray" technology; see Stoughton, 2005) allowed an exact assessment of genotype but still only represented a small proportion of the total genome. However, in the 21st century, the difficulty and cost associated with sequencing whole genomes was dramatically decreased by the advent of new technologies, referred to now as "next generation sequencing" (for a review, see Mardis, 2008). These methods typically sequence many fragments in parallel and use a new type of chemistry associated with the quantification of light released when DNA strands are extended ("pyrosequencing"; see Mardis, 2008).

The applications of these genomic technologies in conservation genetics are largely in two categories (see review in Allendorf *et al.*, 2010). The first simply takes advantage of the much greater power available by the very large number of neutral polymorphic sites revealed (e.g., to obtain more accurate estimates of N_e , migration rate, population structure (units of management), and populations dynamics). It would also permit better assessment of introgression toward management against breeding hybrid organisms. Although these applications permit greatly improved resolution, the other category offers something new. Although work on candidate genes has allowed tests for selection at functional genes, sequences from whole genomes will eventually allow functional gene systems important to conservation to be specifically identified and assessed. However, single gene effects based on mutational differences in that gene are likely to be relatively rare. Instead, phenotypes are encoded by multiple genes, genes may play different roles in different genomic or environmental

contexts, and phenotype is usually determined to some extent by environment. Further, some genes control the expression of other genes (so called nonadditive interactions), and these expression profiles may be the relevant measure for assessing local adaptation. In some cases, differences in phenotype will be due to the ability of organisms with a given genotype to express different phenotypes, known as “phenotypic plasticity”. Genomic methods make the analysis of all of these aspects possible but not less complicated. The researcher investigating a whole genome is typically confronted with billions of bases of DNA, and one of the greatest challenges for the future will be finding the means to efficiently and effectively analyze those data. In spite of the limitations so far, the potential is great, and already significant advances are being made. Hundreds of nonhuman whole genome sequences are now available or are in progress at different levels of resolution, and a consortium of scientists is promoting the sequencing of 10,000 species (the Genome 10K project; Haussler *et al.*, 2009). A major objective of the Genome 10K project is to promote biodiversity conservation.

Work to promote the conservation of functional diversity will be able to employ methods that permit the identification of loci under selection on a comparatively large scale. As described previously, there is a predictable relationship between diversity within populations and genetic differentiation between them (see Foll and Gaggiotti, 2008). When thousands of loci can be investigated at the sample time, then an assessment of this relationship can be undertaken for all loci at once, and the significance of outliers assessed, indicating candidate genes that may be under selection (Figure 4). So, rather than starting with the gene based on known function, it is possible to search for genes showing a signal for selection and then consider their function in the context of quantifiable differences in environmental or ecological factors. One of the first studies to apply this approach using genomic technologies involved a study of marine and freshwater populations of the three-spine stickleback (*Gasterosteus aculeatus*; Hohenlohe *et al.*, 2010). The authors used a technique that sequences a subset of DNA from across the genome (but still including millions of base pairs) to identify SNP loci that can be screened among individuals at the population level. Hohenlohe and co-authors identified more

than 45,000 SNPs and screened them among 100 fish from both marine and freshwater populations. They identified numerous loci that showed evidence for selection and found parallel changes that suggest a common signature for adaption to freshwater, indicating that large random mating marine populations had repeatedly given rise to freshwater populations, and that the adaptive mechanisms permitting this were comparable for independent events. This and similar studies in future will provide conservation biologists with key information about how biodiversity can best be protected. It will likely be possible to identify genes’ relevant major processes such as climate change, and it is already clear that populations showing little differentiation at neutral genetic markers may be differentiated at loci that are under selection (e.g., White *et al.*, 2010), reflecting functional diversity that should be conserved. Conservation genetics is a field that is especially well-served by advancing technologies and is of increasingly critical importance as anthropogenic impacts increase and natural populations decline.

Appendix

List of Courses

1. Conservation Biology
2. Molecular Ecology
3. Population Genetics
4. Evolutionary Biology
5. Biogeography

Figure 4 Under neutral expectations, there is a predicted relationship between the diversity within and the genetic distance between populations. This illustration shows how multiple loci can be screened for this relationship, where outliers outside 95% (light gray line) or 99% (dark gray line) confidence limits indicate loci likely under selection (ringed blue dots in the figure).

Glossary

Directional selection Natural selection that favors phenotypes that differ from the current mean phenotype of a population in one direction (e.g., those that are larger than the current mean).

Disruptive selection Natural selection that favors phenotypes that deviate in either direction from the current population mean.

Dominance Phenotypic effect of a particular heterozygous combination of two alleles at a single locus that deviates from the mean of the two homozygous phenotypes.

Epistasis Phenotypic effects of particular combinations of alleles at two or more loci that differ from the sum of additive effects of these alleles (i.e., the analog of dominance for more than one locus).

Gene flow The influx of genetic variants into a local gene pool as consequence of immigration of individuals or gametes (i.e., pollen).

Genetic drift Stochastic change in allele frequencies at a given locus from generation t to generation $t + 1$ due to the chance events that affect the number of offspring produced per parent in generation t . The effect of genetic drift on allele frequencies and, by extension, on population mean phenotypes increases with decreasing population size.

Genetic linkage map For a given taxon, a map of genetic marker loci that are arrayed based on the recombination rates among them. Recombination rates are estimated from crossing-over events in controlled crosses. Given a sufficiently high marker density, the resulting linkage groups correspond to chromosomes.

Polymorphism The co-existence of two or more distinct variants in a population either in the form of alleles for a given locus or as distinct phenotypes.

Stabilizing selection Natural selection against phenotypes that deviate from the current population mean.

Introduction

Historical Sketch

Ecological genetics is a multidisciplinary endeavor with the aim to understand phenotypic adaptation in response to specific selective agents in a particular ecological setting and in terms of the underlying genetic changes. While this definition has remained largely constant over the past 50 years since the publication of the first treatise on the topic (Ford, 1964), there have been marked shifts in the kinds of traits under study and in the time scales of adaptation that have been considered. Given the available methodology at the time, Ford (1964) presented mainly studies of strongly selected visible polymorphisms with a simple genetic basis, such as banding patterns in snails, cryptic coloration in moths, mimicry in butterflies, and heterostyly in primroses. He concluded that a wealth of evidence “forces us completely to readjust our thoughts on evolution and to recognize that a population may adapt itself very rapidly to changed conditions” (p. 296). This was in contrast to the prevailing view that evolutionary change and ecological interactions took place on different time scales and that species could therefore be viewed as fixed entities from an ecological perspective. However, this view was to change gradually over the next decade (Brussard, 1978).

Antonovics (1976) eloquently advocated a “new ecological genetics” that abandoned the distinction between ecological and evolutionary time scales and viewed biological communities “as consisting of evolving components” (p. 239). The scope for empirical tests of this assertion was greatly enlarged with the introduction of quantitative genetics to the study of

evolution in natural populations (Lande, 1979, 1982; Lande and Arnold, 1983). Continuously varying phenotypes including life history traits such as rates of growth and development and schedules of birth and death became amenable to evolutionary analysis. Finally, Endler’s (1986) comprehensive review of empirical studies proved that directly observable adaptive responses to natural selection in the wild were not uncommon.

Since then, empirical studies of contemporary adaptive evolution have been published at an increasing rate and with ever finer resolution of the contributing processes. Thanks to the recent availability of abundant, highly variable genetic markers, phenotypic change can be analyzed in the context of a known genetic population structure that is inferred from the distribution of neutral marker alleles. Moreover, marker-based linkage maps can be used to study the genomic distribution of genetic effects ($\approx$ loci) that underlie a continuously varying trait. The identification of such effects can serve as a first step toward pinpointing the molecular basis of a given adaptive response. Moreover, genetic markers allow for the construction of pedigrees in intensively studied natural populations. Such pedigrees are prerequisites for the analysis of phenotypic traits with the so-called animal model (Kruuk, 2004, Kruuk *et al.*, 2008). Over the past decade, the application of this model to studies of natural populations has transformed the analysis of microevolutionary processes. It represents a powerful statistical tool with which to dissect the complexities of phenotypic trait variation that lie at the very heart of ecological genetics. Additive genetic variation, the key component of inheritance, can be estimated alongside maternal effects, effects of sex, age, spatial heterogeneity, or temporal trends (see Wilson *et al.*, 2010 for a concise, nontechnical introduction).

Scope and Outline of the Article

This article takes a microevolutionary perspective on adaptive phenotypic evolution, i.e., it concentrates on processes that are observable on a maximum time interval of roughly 100 years (Thompson, 1998) and mostly within the time frame of a researcher's career. Whenever possible examples are drawn from long-term field studies, because they offer priceless insight into the temporal dynamics of ongoing evolutionary change and allow for a dissection of multiple cooccurring processes. Given the focus on adaptive change brought about by either directional or disruptive selection, any unqualified use of the term selection refers implicitly to these two modes. However, it is worth keeping in mind that stabilizing selection also plays an important role in natural populations. Furthermore, the article focusses on microevolutionary change within populations. It can often be the starting point of regional differentiation and may ultimately contribute to the formation of new species. These processes are considered in other articles of this encyclopedia. Finally, this article is about concepts and insights from empirical studies rather than about methodological issues such as the estimation of allele frequencies, gene flow rates, or heritabilities. These are discussed in detail in several text books (Falconer and Mackay, 1986; Lynch and Walsh, 1998; Conner and Hartl, 2004; Lowe *et al.*, 2004).

The first three sections lay out the building blocks of any microevolutionary analysis: the amount of heritable genetic variation in the target species, the strength of natural selection and the rate and pattern of any adaptive response. Next, genetic correlations are discussed as sources of trade-offs that can limit phenotypic evolution. Strategies of and limits to microevolution in heterogeneous environments are the themes of the sections on phenotypic plasticity and local adaptation, respectively. The final two sections present insights from the genetic dissection of phenotypic traits and from analyses of the wider ecological implications of contemporary adaptive evolution.

Genetic Variation for Phenotypic Traits in Natural Populations

Every phenotypic trait results from a complex interplay of many gene products that influence its mature expression over the course of ontogeny. A mutation at any one of the underlying loci can in principle alter a trait. Yet only those genetic loci that are polymorphic at any one time contribute to the trait's heritable variation. In the context of any (micro-) evolutionary analysis, the focus is thus on the genetic basis of phenotypic variation of a given trait, not on the full complement of genes that are involved in the trait's expression. This implies that the inheritance of a trait either as a distinct polymorphism or as a continuous spectrum of phenotypes is partly a function of the number and effects of genetic variants that segregate in a population at any one time. This genetic architecture may change if, for example, an allele of large effect is fixed by selection.

If discrete phenotypic variation is based on polymorphisms at one or two loci, then crossing experiments can in principle map trait values to alleles and the heritable variance

Box 1 Quantitative genetics

Quantitative genetics represents a statistical analysis of the resemblance among relatives to uncover the causal components of phenotypic variation and to predict phenotypic responses to natural or artificial selection either for single or for multiple, correlated traits. At its core is a model that assumes the existence of a large number of polymorphic loci with alleles of small and mostly additive effect. The particular set of alleles carried by an individual causes its phenotype P to deviate from the population mean phenotype μ by a certain amount. This deviation is called the individual's genotypic value G and has a population mean of zero. Any nongenetic influences on the phenotype are modeled similarly as the environmental deviation E , which is assumed to be normally distributed with mean zero. Consequently, an individual's phenotypic value P is defined as

$$P = \mu + G + E$$

The summation over many small genetic effects and the assumptions about E ensure that the resulting distributions of P , G , and E are normally distributed. This framework thus allows for an analysis of phenotypic variation in terms of a small number of parameters (i.e., means and variances) without any knowledge of the underlying genetic detail. Empirical support for this model comes partly from the common observation of normally distributed phenotypes in nature and from the immense utility of quantitative genetics for plant and animal breeders.

Clearly, gene action is not necessarily additive. At a single locus, one allele may be partly or entirely dominant over another and there may be epistatic interactions among alleles at two or more loci. Under these conditions, the effect of an allele depends on the genetic background in which it occurs. Nonadditive gene action is incorporated into the model by partitioning the genotypic value into an additive component A , a dominance deviation D and a deviation due to epistatic interactions, I :

$$G = A + D + I$$

The additive effect of an allele is defined accordingly as the average deviation from the population mean phenotype caused by a single copy of that allele. Just as the overall mean phenotype depends on the allele frequencies at all underlying loci, the average effect of an allele depends on the frequency distribution of genetic backgrounds in the population. It is thus affected by nonadditive gene action and may vary from one population to another. For a given phenotype, the sum of all additive allelic effects is A .

Because genotypes are broken up and reshuffled in the process of sexual reproduction, dominance and epistatic effects on parental phenotypes are not passed on to the offspring. The laws of inheritance thus revolve around the additive genetic variation. The additive component A of an individual's phenotype is defined as its breeding value. It predicts the mean phenotype of its offspring and is therefore in principle measurable. Finally, the proportion of the total phenotypic variation V_P that is due to additive genetic variance V_A (or, equivalently, to the variance in breeding values) is defined as the trait's heritability h^2 :

$$h^2 = V_A / V_P$$

Falconer and Mackay (1996) and Lynch and Walsh (1998) present detailed treatments and extensions of this model.

in the trait follows directly from the allele frequencies in the population. More typically, variation in a trait is based on many polymorphic loci and also reflects substantial environmental influences. Quantitative genetics provides the necessary framework in which to analyze such traits (see Box 1 for a brief summary of the basic model). Over the past 30 years, quantitative genetic studies have demonstrated the existence of substantial additive and thus heritable genetic variation for

Box 2 Estimating the strength of selection on quantitative traits

In its original univariate form, the so-called breeder's equation predicts the response of a trait to selection given estimates of the trait's heritability h^2 (cf. **Box 1**) and the strength and direction of selection on that trait:

$$R = h^2 S$$

where the selection differential S is defined as the difference between the mean phenotype before selection, μ , and that after selection within one generation. Equivalently, S represents the phenotypic covariance between the trait and relative fitness, where relative fitness is distributed with mean 1. The selection response R is the difference between μ and the mean phenotype in the following generation. This model can predict R provided that selection acts directly on the trait under consideration (z_1). It will fail, however, if the shift in the mean of z_1 in the parent generation results from a merely phenotypic covariance with a second trait z_2 that is in fact under selection. In this situation, there can be no selection response in z_1 because there is no additive genetic covariance between both traits that would reflect a (partially) shared genetic basis.

The example points to the more fundamental issue that individual traits do not evolve in isolation. Particularly, additive genetic covariation in a number of traits implies that selection on any one trait should produce a correlated response in the others. To determine which traits actually cause variation in fitness and to predict the responses to direct and indirect selection, a broader modeling framework is needed.

To this end, Lande and Arnold (1983) derived a multivariate analog of the breeder's equation. Recall that the heritability is the quotient of additive genetic variance over phenotypic variance, V_A/V_P . Each of these terms is now replaced by a matrix, which contains for the set of measured traits the appropriate variances (diagonal elements) and pairwise covariances (off-diagonal elements). Of particular interest is the additive genetic matrix **G**, which contains the variances and covariances of breeding values (see **Box 1**). It encapsulates not just the per-trait amount of genetic variation on which selection can act but also the interdependencies among traits that are due to a shared genetic basis and that may either enhance or constrain the selection response of any one trait. The matrix **P** is the phenotypic analog of **G**. The multivariate breeder's equation is thus

$$\mathbf{R} = \mathbf{G}\mathbf{P}^{-1}\mathbf{S}$$

where **R** and **S** are vectors of selection responses and differentials, respectively. This equation can be rewritten as

$$\mathbf{R} = \mathbf{G}\boldsymbol{\beta}$$

where **β** is a vector of selection gradients which express the strength of direct selection on each trait. Selection gradients can be estimated as partial regression coefficients when relative fitness (or a component thereof) is regressed on the set of measured traits. They quantify the strength of directional selection on a given trait when all other traits are held constant. Quadratic terms to estimate either stabilizing or disruptive selection can be added to the regression model. Note however, that these are not easily incorporated into the breeder's equation.

While the consideration of multiple traits should generate much improved estimates of selection strengths and responses, the breeder's equation typically fails as a predictive tool when applied to natural populations. Violations of the model assumptions (Lande and Arnold, 1983) are partly responsible for this. Phenotypes, breeding values and environmental deviations are assumed to follow a multivariate normal distribution (or can be transformed into such). Highly correlated traits mean that the inverse matrix $\mathbf{P}^{-1}$ cannot be found, selection gradients cannot be estimated and the dimensionality of the model needs to be reduced (e.g., through the use of principal components). Moreover, estimates of selection strengths and responses will still be in error to the extent that additional pertinent traits are missing from the analysis. Finally, the variance-covariance matrices apply to the base population before selection acts. Different environmental conditions in the offspring generation may alter these matrices to the extent that **R** cannot be correctly predicted.

Endler (1986) and Mitchell-Olds and Shaw (1987) discussed a range of statistical issues that follow from these assumptions. Moreover, since "missing traits" can lead to erroneous inference of selection on one or more of the measured traits, these authors argued that the results of the regression analysis should be validated in the context of a longer term research program that includes detailed field observation and, ideally, experimental manipulation. Without this context, estimates of selection gradients are in Endler's words (1986, p. 201) akin to "refined alchemy." The problem of causation and the common discrepancy between predicted adaptive change and observed stasis have recently prompted a more fundamental critique of the current use of the breeder's equation in observational studies of natural populations. Morrissey et al. (2010) specified the condition under which the breeder's equation will arrive at correct inferences of causal factors and selection responses and provided examples of commonly encountered situations in nature that violate this condition. The authors advocated an alternative approach to predict selection responses based on the Robertson-Price identity (Robertson 1966; Price, 1970).

practically any trait that has been studied (Mousseau and Roff, 1987; Roff, 1997). However, there are a few notable exceptions (Blows and Hoffmann, 2005): low heritabilities were found, for example, for mass-specific metabolic rates in mammals and there are a small number of cases in which artificial selection experiments did not produce a phenotypic response.

Estimates of heritability (**Box 1**) are typically used to predict the response of a trait to selection. According to the so-called breeder's equation, this response is equal to the product of heritability and selection strength (**Box 2**). When different types of traits are compared, morphological characters have the highest and life history traits the lowest heritabilities (means: 0.461 and 0.262, respectively, Mousseau and Roff, 1987). This discrepancy between morphology and traits

closely correlated with fitness is widely observed not just under controlled laboratory conditions but also in wild, unmanipulated populations (e.g., Merilä and Sheldon, 2000). It agrees with the expectation that persistent selection toward an optimum should erode additive genetic variance in fitness and in traits associated with it. However, this interpretation is not supported by more detailed analyses. Instead, the lower heritability in fitness-related traits is primarily due to greatly increased residual variation (V_R), which subsumes non-additive and environmental effects (Houle, 1992; Campbell, 1997; Merilä and Sheldon, 2000; Coltman et al., 2005; Teplitsky et al., 2009). The level of additive genetic variation may either show no correlation with the fitness association of a trait (Campbell, 1997; Kruuk et al., 2000; McCleery et al.,

2004; Coltman *et al.*, 2005) or even increase with it (Houle, 1992; Merilä and Sheldon, 2000, but see Teplitsky *et al.*, 2009 for a counter example).

These patterns may derive from the particular nature of fitness itself, a composite trait that is expressed late in life. Compared to ordinary traits, it should reflect the cumulative environmental variation over an individual's lifespan (increased V_E) as well as genetic variation at a larger number of loci. It might thus represent a large "mutational target" (Houle *et al.*, 1996, increased V_A). Moreover, low genetic variation in total fitness does not rule out substantial additive genetic variation in fitness components, such as survival or fecundity, if there are negative genetic correlations among them (Charlesworth, 1987, *see* Genetic Correlations).

The heritability of a given trait can vary as a function of environmental conditions. In comparisons between benign and stressful conditions, studies of size-related traits in *Drosophila* initially suggested that harsh conditions caused an increase in heritability (Hoffmann and Parsons, 1991) but analogous studies in birds showed the opposite trend (Hoffmann and Merilä, 1999). More recent detailed analyses of genetic variance components across a range of animal taxa have corroborated the pattern seen in birds (Charmanier and Garant, 2005): overall, stressful conditions reduce the heritability of a trait. The effect is stronger in size related as opposed to fitness-associated traits and can be due to a reduction of V_A , an increase in V_E , or a combination of both. To explain these effects, it has been suggested that harsh conditions (1) prevent individuals from reaching their genetic potential and (2) create increased local variation in habitat quality (Hoffmann and Merilä, 1999; Charmanier and Garant, 2005). More generally, these studies illustrate that the ecological context plays an important role in the phenotypic manifestation of genetic variation (Charmanier and Garant, 2005; Ellegren and Sheldon, 2008).

The Strength of Natural Selection: Point Estimates

Selection on Discrete Polymorphisms: An Example

In the case of discrete polymorphisms, the strength of directional selection on a given phenotype can be measured from its rate of increase or decrease in frequency. Because genotypes can be inferred from phenotypes in this case, there is no need to distinguish between the strength of selection and the selection response, i.e., the shift in mean phenotypes from one generation to the next. For example, the melanic morph of the peppered moth (*Biston betularia*) reached local frequencies close to one in Britain only 50 years after it was first observed, which suggests a 30% higher fitness relative to the light-colored wildtype (Haldane, 1924). The fate of the dark morph which is tightly linked to levels of air pollution has now turned and its rate of decline implies a selective disadvantage of similar but somewhat lower magnitude (Cook and Turner, 2008). This classic case of "industrial melanism" continues to be a textbook example of evolution in action (Majerus, 2009).

A Review of Selection Gradients

In continuously varying traits, the strength of directional selection is estimated from a linear regression of a measure of

fitness, such as survival or fecundity, on individual phenotypes. The slope of this regression estimates the selection differential or, if several traits are analyzed simultaneously, the selection gradient for a given trait (*see* Box 2).

An influential review of published selection gradients (Kingsolver *et al.*, 2001) found that their absolute values followed an exponential distribution: most estimates were small, but moderate to large values were also observed. The change in relative fitness per phenotypic standard deviation (SD) had an overall mean of 0.22 and a median of 0.16. About 13% of the estimates were greater than 0.5. Note that the median estimate implies substantial fitness variance, because a trait may vary over several SDs within a population (Hereford *et al.*, 2004). Moreover, assuming a heritability of 0.5, sustained directional selection of this strength would cause the trait mean to shift by 3 SDs within 50 generations (Kingsolver and Pfennig, 2007).

The review also showed that selection was on average stronger on morphology than on life history or phenological traits. However, this need not reflect a true biological pattern other than that morphology is easier to estimate accurately. In studies that spanned months or years (as opposed to days), larger estimates were observed when fitness was measured in terms of fecundity or mating success as opposed to survival (Hoekstra *et al.*, 2001). Finally Kingsolver *et al.* (2001) also estimated the strength of stabilizing versus disruptive selection and found that these modes were detected with equal frequency. This observation challenges the commonly held view that stabilizing selection should be the rule and disruptive selection the exception.

Potential Biases in Estimated Selection Strengths

Kingsolver *et al.* (2001) discuss a number of reasons why the estimates of linear selection gradients may be biased upward. They are probably not a random sample of selection strengths in nature, because researchers focus on study systems in which they suspect selection to be operating. The majority of studies had small sample sizes which may have introduced biases (Hersch and Philipps, 2004, but see Knapczyk and Conner, 2007). Finally, almost all studies measured fitness components (survival, mating success, or fecundity) only. Their less than perfect correlation with total fitness necessitates a downward adjustment of the selection estimates (Hereford *et al.*, 2004).

However, there are also reasons to believe that natural selection may actually be stronger than suggested by the review. Hereford *et al.* (2004) showed that standardizing selection gradients by the phenotypic SD (as in Kingsolver *et al.*, 2001) confounds the strength of selection with the ability of the population to respond to it. The authors advocated instead standardization by the mean phenotype, which expresses the change in relative fitness for a proportional change in the trait. This approach is applicable to traits with a non-arbitrary minimum trait value (i.e., true ratio traits, e.g., body size with a minimum of zero, but not "flowering date"). For the appropriate subset of the Kingsolver *et al.* (2001) data, standardization by the mean yielded a median linear selection gradient of 0.31, which implied selection that is 31% as strong as selection on fitness itself (Hereford *et al.*, 2004).

Furthermore, Blows and Brooks (2003) detected strong non-linear directional selection on certain trait combinations in the dataset of the review.

One final and important source of bias in estimating selection strengths comes from environmental covariances between fitness and trait, because they can imply selection where in reality there is none. Price *et al.* (1988) discussed the hypothetical example of a bird population in which individuals that breed earlier in the spring produced larger clutches. This apparent selection on breeding date may result from purely environmental variation in overall “condition” such that some birds have sufficient resources to produce large clutches early in the year while others cannot but breed later and lay fewer eggs. The problem can in principle be remedied by estimating selection based on breeding values (approximated as offspring means per family) rather than individual observations (Rauscher, 1992). To the extent that family members are randomized over local environmental conditions, this approach eliminates the environmental covariance (but see Postma, 2006 and Hadfield, 2008 for an important caveat). Based on studies of three annual plants, Stinchcombe *et al.* (2002) found that environmental covariances produced significant and substantial biases in 25% of the estimated selection gradients. Path analysis represents an alternative approach to disentangling the causal factors underlying (apparent) selection on a given trait (Scheiner *et al.*, 2002, see also Kruuk *et al.*, 2003).

Thus, there is at present no straightforward conclusion about the strength of selection in unmanipulated natural populations in a single generation. While strong selection per trait and generation may occur only occasionally, it appears that mean phenotypes quite often do not coincide with the current, local optimum.

Patterns of Selection and of Adaptive Responses

Examples of Rapid Evolution

Cases of abrupt changes in ecological conditions have provided the most clear-cut examples that heritable genetic variation and directional natural selection can bring about observable and adaptive phenotypic change. When Trinidadian guppies (*Poecilia reticulata*) were translocated into sites with reduced predation pressure (Endler, 1980), two such replicate populations evolved within 12 and 18 generations, respectively, in the expected direction of earlier sexual maturity and smaller size (Reznick *et al.*, 1997). Recent anthropogenic habitat change has caused classic examples of rapid phenotypic evolution, such as industrial melanism (see Selection on Discrete Polymorphisms: An Example), heavy metal tolerance (Antonovics *et al.*, 1971) and crop mimicry in plants (Barrett, 1983). Similarly, species introductions due to human transport have provided numerous examples of rapid evolution of both new arrivals (Lee, 2002) and residents (Strauss *et al.*, 2006), including novel host use, life history adaptations, and altered defenses against predators (Thompson, 1998).

One of the fastest responses to natural selection is the gradual establishment of a latitudinal cline in body size in North American populations of *Drosophila subobscura* within

20 years after their introduction from Europe (Huey *et al.*, 2000). At the end of this period, female wing length clines in Europe and North America were statistically indistinguishable but, intriguingly, based on changes in different parts of the wing. Overall, recent phenotypic changes in response to anthropogenic disturbances were larger on average than those associated with “natural” environmental perturbations, but this increase was partly due to phenotypic plasticity (see Phenotypic Plasticity, Hendry *et al.*, 2008).

Fluctuating Selection

When one considers the rates of phenotypic change more generally, a discrepancy emerges: extrapolation of the responses to contemporary selection predicts much faster long-term phenotypic change than is actually observed in the fossil record (Gingerich, 1983; Hendry and Kinnison, 1999). Selection that varies in strength and direction over time represents one possible way out of the dilemma (Thompson, 1998; Bell, 2010). This hypothesis of fluctuating selection is *a priori* appealing given ubiquitous environmental heterogeneity (Connell and Sousa, 1983). Theoretical support comes from Estes and Arnold's (2007) demonstration that macroevolutionary patterns of phenotypic change and divergence can be produced by a microevolutionary model in which the population mean phenotype tracks the bounded meanderings of the local optimum around an overall mean. Finally, a recent survey reported extensive temporal variation in selection strengths and directions (Siepielski *et al.*, 2009). However, Morrissey and Hadfield (2012) found that sampling error was a major source of the observed variation and arrived at a more cautious assessment based on their reanalysis of the data. There is consensus, however, that better knowledge of the causative agents of natural selection would greatly help to clarify the role of fluctuating selection, especially *vis à vis* the alternative hypotheses of drift and immigration (Bell, 2010). In general, it has proven much easier to demonstrate that particular environmental conditions tend to select for certain phenotypic attributes than to identify the particular habitat features that exert the selection pressure.

Empirical demonstrations of fluctuating selection necessarily rely on long-term studies with sufficient temporal resolution (see Bell, 2010 for a list of examples). Females of the freshwater copepod *Onychodiaptomus sanguineus* switch in the spring from producing eggs that hatch immediately to those that undergo diapause (Hairston and Dillon, 1990). The switch date is highly heritable ($h^2=0.48$) and is linked to the seasonal increase in fish activity and thus predation: Diapausing eggs are safe from fish, but females that switch too early forego one or more rounds of reproduction. The optimal switch date in a given year also depends on fish density. Hairston and Dillon (1990) documented several correlated cycles of fish density and mean switch date over a 10-year period in a small North American lake. Interestingly, the response to selection was dampened by the influx of individuals from the pool of diapausing eggs (Ellner *et al.*, 1999), which differed in their mean switch date from the current optimum.

The best available time series of evolving phenotypes, selection differentials and pertinent ecological parameters

documents the evolution of body size, beak size, and beak shape in two species of Darwin's finches (*Geospiza fortis* and *Geospiza scandens*) on the Galápagos island of Daphne Major (Grant and Grant, 1989, 2002). Data from the first 30 years of the study produced evidence of both abrupt and more gradual increases and decreases in trait means as well as periods of stasis. These patterns differed between the two species (Grant and Grant, 2002). The main causative agent of selection was variation in food supply that was driven in turn by fluctuations in rainfall levels ranging from severe droughts to the unusually heavy rains of an El Niño event. Significant selection differentials for body size were observed about every 3 years in *Ge. fortis* and runs of significant unidirectional selection in any measured trait lasted no longer than 3 years. The distribution of selection gradients was comparable to the published large-scale survey (Kingsolver *et al.*, 2001): most of them were small ($\beta < 0.15$ phenotypic SDs) and only a few were large ($\beta > 0.5$ SD). Over the 30-year period, however, they contributed to a marked net change in all trait means with one exception (beak size in *Ge. fortis*).

Lack of an Evolutionary Response

The study of Darwin's finches is remarkable also, because the phenotypic responses to natural selection could be accurately predicted from estimated heritabilities, selection gradients, and genetic correlations among the measured traits (Grant and Grant, 1995, 2002). Overall, this is the exception rather than the rule in quantitative genetic studies of natural selection in the wild. Predictions of this quality are usually restricted to studies under controlled laboratory conditions (Lynch and Walsh, 1998). Particularly, there are numerous examples from unmanipulated natural populations in which substantial heritabilities and selection gradients failed to produce a change in the trait mean (Merilä *et al.*, 2001). Careful dissection of some of these cases has illustrated how the interplay between organismal features and environmental variables affects the efficacy of natural selection.

A contrast between apparent selection and observed phenotypic change was discovered in an analysis of red deer (*Cervus elaphus*) antler size based on a 30-year study on the Scottish island of Rum. By applying the animal model, Kruuk *et al.* (2002) showed that antler size was substantially heritable ($h^2 = 0.33$) and also significantly correlated with lifetime breeding success ($\beta = 0.445$ phenotypic SD). From these figures, antler size was predicted to increase over the course of the study, but instead it showed a decrease that was driven by increasing population density. After correction for the latter effect, there was no evidence for a genetic correlation between antler size and fitness and no indication of any evolutionary change in this trait. Instead, the data strongly suggested that the phenotypic correlation between antler size and fitness came about via a third, unmeasured, condition-dependent trait. Here, as in the hypothetical example of egg-laying dates in birds (see Potential Biases in Estimated Selection Strengths), environmental covariances between fitness and a given trait can generate the spurious inference of natural selection in action (see also Kruuk *et al.*, 2003; Morrissey *et al.*, 2010).

This example also illustrates how contrasting trends of phenotypic versus genetic change can obscure ongoing evolutionary processes. Classic examples are phenotypic clines of increasing body size and development time with altitude that mask trends in genotypic values in the opposite direction. For example, mountain populations of green frogs (*Rana clamitans*) face a much shorter larval growing season than their conspecifics in the lowlands. This forces them to overwinter once or even twice before metamorphosis. The resulting intense selection for rapid development is revealed under constant laboratory conditions, where tadpoles from upland populations develop significantly faster than those from the lowlands and especially so at low temperatures (Berven *et al.*, 1979). Such counter-gradient selection (for a review see Conover and Schultz, 1995) can result in phenotypic homogeneity, when environmental and genetic influences balance each other. Similarly, phenotypic stasis within a given population over time might be caused by an ongoing evolutionary response to directional selection that balances an environmental trend in the opposite direction.

Temporal variation in heritability contributed to an unexpectedly low selection response in an intensely studied population of Soay sheep (*Ovis aries*) on one of the St. Kilda islands (Wilson *et al.*, 2006). Birth weight in these sheep is both heritable and strongly positively associated with the survival of lambs during their first summer. Nevertheless, it showed no increase over the 20-year study period. Overall, variation in density and climatic conditions caused substantial annual variation in the total first-summer survival. This variation affected both the heritability and strength of selection on birthweight: strong selection and low heritability coincided in low survival years, whereas weak selection and increased heritability were observed in good years. The resulting negative correlation between the two independent variables in the breeder's equation reduced the maximum possible response to selection.

There is an interesting twist in this story. Total heritability in birthweight has two components: one based on the additive genetic variance of the trait in the offspring and a second one due to genetic maternal effects. Maternal effects comprise all means by which a mother's phenotype influences the phenotype of her offspring over and above the additive effects of the transmitted genes. Maternal effects used to be thought of mainly as components of environmental variance, as in the case of larger offspring from females that are in good condition. However, there can also be genetic maternal effects due to heritable phenotypic variation among females that contributes to the variation in some measure of offspring phenotype. Any component of maternal investment and parental care might in principle display such effects, and they are increasingly recognized as an important variance component in natural populations (for a review see Räsänen and Kruuk, 2007). In the case of the Soay sheep, temporal variation in total heritability of birthweight could indeed be attributed to maternal genetic effects. Under good environmental conditions, there was relatively more heritable variation in the mothers' ability to promote the *in utero* growth of their offspring.

Taken together, the examples in this section illustrate that point estimates of heritabilities and selection strengths

provide only a rough, first approximation of the scope for microevolutionary change in natural populations. Temporal variation in either of these variables can considerably alter the course of ongoing adaptive phenotypic change, and insufficient temporal resolution in a given dataset may miss some or all of the dynamics. Furthermore, a purely phenotypic correlation between a trait and fitness gives the erroneous impression that the trait plays a causative role in fitness variation. Finally, spatial or temporal trends in environmental effects can override or balance genetic change in the opposite direction. An additional impediment to adaptive phenotypic change is considered in the next section.

Genetic Correlations

Pleiotropy

While there is an effectively infinite number of traits that ecologists and evolutionary biologists might choose to measure on a given organism, the number of developmental pathways that lead to their manifestation is clearly finite. This suggests widespread genetic interdependencies among traits due to a partially or entirely shared genetic basis. Genetic variation that affects the expression of any one trait is likely to affect others as well, a condition known as pleiotropy. Comparisons of estimated mutation rates per trait versus per genome and considerations of total fitness variance within populations similarly argue for widespread pleiotropy (Barton, 1990). Pleiotropy causes genetic correlations among traits with a shared genetic basis which are measurable as correlations between breeding values. As a consequence, direct selection on one trait will cause indirect selection in any correlated trait. Selection gradients (see A Review of Selection gradients and Box 2) were devised to estimate the strength of direct selection on a given trait in such cases. Note that a genetic correlation can be the result not just of pleiotropy but also of tight genetic linkage between loci that affect different traits.

Genetic correlations can impede the response to joint selection on several correlated traits (antagonistic pleiotropy). Of particular interest is the case of a genetic trade-off in which the fitness gain due to selection on one trait is cancelled by an associated fitness loss in a second, correlated trait. Antagonistic pleiotropy and genetic trade-offs feature prominently in the context of ecological specialization (see e.g., Hawthorne and Via, 2001), life history theory (see Life History Trade-Offs) and sexually antagonistic selection (e.g., Foerster *et al.*, 2007).

Genetic Correlations: A Case Study

Limited genetic variation for certain trait combinations is a recurring theme in the study of flower shapes. In the wild radish (*Raphanus raphanistrum*), the lengths of filaments and of the corolla are highly correlated such that anthers protrude from the corolla by a certain amount (the so-called anther exsertion). The strength of the genetic correlation is illustrated in a plot of filament length against corolla length: individual breeding values cluster along a straight line with positive slope (Conner,

2003). In other words, most genetic variation is arrayed along that one axis (=flower size), whereas little genetic variation exists along the perpendicular axis that represents variation in anther exsertion. Indeed, the latter trait is under stabilizing selection in the field, because plants with intermediate trait values achieve the highest seed-siring success (Morgan and Conner, 2001). The current correlation pattern may thus reflect a shared developmental pathway and/or past selection (Conner, 2006). However, the genetic correlation between filament and corolla length ($r=0.85$) did not pose an absolute constraint ($r=1$ or $r=-1$) and anther exsertion did respond to five generations of artificial selection (Conner 2003).

Life History Trade-Offs

Genetic trade-offs are key components of life history theory. Classic examples are egg size versus egg number and survival versus reproduction. The most clear-cut evidence for their existence comes from artificial selection (Fry, 2003) and manipulative experiments (Zera and Harshman, 2001). *Drosophila melanogaster* that have been artificially selected for early reproduction have a shorter lifespan. When egg production was experimentally suppressed in females at the end of the selection experiment, the mortality difference between early and late reproducing selection lines disappeared, which established the direct causal link between early investment into eggs and increased mortality later in life (Sgro and Partridge, 1999). Experimental manipulations of the side-blotched lizard (*Uta stansburiana*, Sinervo, 1999) illustrated how hormones mediate the trade-off between egg size and egg number in this species. Such trade-offs are expected to leave their mark on additive genetic correlations among traits within populations. In the case of the lizards, one might expect that V_A for egg number should entail measurable negative genetic and phenotypic correlations between the number and size of eggs. However, numerous attempts to demonstrate trade-offs in the form of negative genetic correlations across a wide range of taxa and traits have produced surprisingly few clear-cut examples.

Several hypotheses have been advanced to explain this puzzling pattern. While an individual necessarily faces a trade-off when allocating a given resource pool to competing organismal functions, no such trade-off need be apparent at the population level. This will be the case when individuals differ not only in their allocation rules but also in the amount of resources at their disposal. Those that have acquired a larger resource pool can allocate more to each fitness enhancing trait, which results overall in a positive correlation between these traits (van Noordwijk and de Jong, 1986). Using a standard modeling framework for quantitative traits, Houle (1991) showed that a simple dichotomy between acquisition and allocation loci can produce either negative or positive genetic correlations depending on the relative number of loci in each category. Trade-offs may also be masked when there is a hierarchy of allocation decisions (Worley *et al.*, 2003). Allocation to somatic growth versus reproduction will often precede decisions regarding, for example, size versus number of offspring or, in hermaphrodites, investment into male versus female function. In such a hierarchy, positive genetic

correlations between the traits that trade-off later in life can arise if the population mean moves toward the overall optimal allocation scheme and if there is relatively more genetic variance for the earlier allocation decision.

Inferring Genetic Constraints from the G Matrix

Pairwise genetic correlations will also be misleading when additional genetic correlations with unmeasured traits play a role. Such “missing traits” pose a problem not just in the prediction of selection responses (Box 2) but also in the inference of constraints from the additive genetic variance–covariance matrix (the G matrix, Box 2). In general, strength and pattern of such constraints depend on the structure of the G matrix as a whole and cannot be inferred from particular matrix elements (for a review see Walsh and Blows, 2009). In fact, some of the trade-offs between component traits are expected to result in positive pairwise covariances (Charlesworth, 1990). Similarly, negative genetic correlations larger than -1 do not translate into “weak” constraints that would merely delay rather than prevent an adaptive response. Pertinent information instead comes from the eigenvalues and eigenvectors of the G matrix. An eigenvalue of zero signifies an absolute genetic constraint in the direction of the associated eigenvector. But even a matrix with only nonzero but highly variable eigenvalues imposes substantial constraints on adaptive evolution.

This is true in particular, if selection acts simultaneously on several correlated traits, a situation that should be commonplace in nature. In that case, only relatively few mutations at the underlying pleiotropic loci are expected to meet the manifold demands of multitrait selection (directional and/or stabilizing) and so increase net fitness (cf. review by Walsh and Blows, 2009). The contrast between successful artificial selection on single traits and the frequently observed lack of a selection response in natural populations may be due, at least in part, to the more complex selection regimes in nature. While we presently lack the necessary data to test this hypothesis, it seems safe to conclude that the sole focus on abundant heritabilities and rare absolute pairwise trade-offs results in an overly optimistic view of adaptive micro-evolutionary change.

Phenotypic Plasticity

An Adaptive Strategy in Heterogeneous Environments

Phenotypic plasticity refers to the observation that a given genotype expresses different phenotypes in different ecological settings. At its most basic level, the concept applies to any differences in trait means between environments. For example, plants may show stunted growth in habitats other than the one to which they are adapted. However, when trait expression in different habitats has been shaped by natural selection, phenotypic plasticity represents an ecological strategy that adapts organisms to heterogeneous environments and forms an integral part of species interactions (Agrawal, 2000). Such adaptive plasticity can range from repeated ontogenetic adjustments in behavior, physiology, or life history to the expression of distinct, irreversible morphologies (polyphenism)

such as fully winged and flightless forms in insects (Harrison, 1980; Roff, 1986), the shade avoidance growth form of plants (Schmitt *et al.*, 2003) carnivorous and omnivorous tadpole morphs of spadefoot toads (Pfennig *et al.*, 2007) inducible defensive morphs of *Daphnia* water fleas (Tollrian and Dodson, 1999) and the seasonally alternating morphs of *Bicyclus anynana* butterflies (Lyytinen *et al.*, 2004).

Theoretical Predictions and Empirical Tests

If phenotypic optima differ across space and time, then a genotype that can reliably express any local optimum at no extra cost is clearly at an advantage and should outcompete all others. Clearly no such organism exists, because it would have an infinite ecological niche. Numerous theoretical studies have specified conditions under which a costly plastic strategy is favored over that of a nonplastic generalist or a collection of locally adapted specialists (reviewed in Berrigan and Scheiner, 2004). Key considerations include the temporal and/or spatial patterns of environmental change, the predictability of such change at the time when developmental “decisions” are made by the organism and the relative frequencies and carrying capacities of each habitat type. The following empirical examples address (1) the assumption that there is a cost to plasticity and (2) the prediction that more variable environments should select for greater plasticity.

To date, many thorough attempts to demonstrate various kinds of plasticity costs (see DeWitt *et al.*, 1998; van Kleunen and Fischer, 2005; Auld *et al.*, 2010 for reviews and classification schemes) have resulted in numerous suggestive trends but only a few clear-cut examples (Auld *et al.*, 2010). In Swedish populations of the common frog, *Rana temporaria*, Merilä *et al.* (2004) detected a cost of accelerated tadpole development in response to simulated pond drying: genotypes that exhibited a stronger plastic response also metamorphosed at a smaller size when reared in controls at a constant water level. This result lends support to the hypothesis that the maintenance of a plastic response system *per se* can be costly. Other examples of demonstrated plasticity costs come from the shade response (Dorn *et al.*, 2000) and flowering time plasticity (Stinchcombe *et al.*, 2004) in *Arabidopsis thaliana*. Despite the limited number of such examples, costs may nevertheless be critical in determining whether phenotypic plasticity in a given trait evolves at all. By the time an established plastic strategy is subjected to scientific analysis, the initial costs may have been absorbed by further adaptive changes (Sultan and Spencer, 2002).

A classic study by Cook and Johnson (1968) tested the hypothesis that greater levels of plasticity are expected in populations from more variable environments. The semi-aquatic lesser spearwort, *Ranunculus flammula*, exhibits so-called heterophylly: partially submerged individuals of this species produce different leaf shapes above versus below the water line. Under controlled conditions, the level of individual plasticity (measured as the difference in shape between the leaf types) increased with the level of environmental heterogeneity both among and within populations. Similarly, two populations of orange jewelweed (*Impatiens capensis*) within 1 km of each other differed in their plastic response to density

in a way that was predicted by estimated selection gradients for plasticity (Donohue *et al.*, 2000; Donohue *et al.*, 2001).

Natural Selection of the Norm of Reaction

A compact graphical presentation of phenotypic plasticity is provided by the norm of reaction (reviewed in Via *et al.*, 1995). It is equal to the mean phenotypes that a given genotype expresses along an environmental gradient (Figure 1). Significant differences among the slopes of reaction norms for a collection of genotypes (cf. Figure 1(b)) are referred to as genotype $\times$ environment interactions ($G \times E$). They indicate genetic variation for plasticity and are frequently observed in natural populations (Pigliucci, 2005). How efficiently this variation can be molded by natural selection depends partly on the patterns of environmental heterogeneity. In a so-called fine-grained environment, in which a range of environmental conditions is typically encountered by an individual during its lifetime, plasticity is a feature of that individual. It can be estimated from repeated measurements and analyzed like any other quantitative trait (Nussey *et al.*, 2007).

In contrast, a coarse-grained environment changes more slowly such that an individual experiences only one of several

environmental states. Consequently, plasticity does not exist at the level of the individual but only at the level of its genotype. Estimation of reaction norms then requires clonal replicates of a genotype or, as a second-best option, full-sib families to be distributed along an environmental gradient. Selection experiments to increase or decrease this type of plasticity (i.e., to alter the slope of the reaction norm) have met with limited, if any, success (Scheiner, 2002), whereas selection on the overall mean of the reaction norm (i.e., its elevation) have generally been successful. These results may be due to the fact that selection above the level of the individual is less efficient (Williams, 1992) or point to genetic constraints (Via and Lande, 1985), such that a significant response is less likely to materialize over the course of a selection experiment.

A striking example of how two populations of the same species can differ in their level of adaptive plasticity comes from two long-term studies of great tits (*Parus major*). In response to increasing spring temperatures over the past few decades, the mean egg-laying date as well as the peak in food abundance (moth caterpillars) have advanced considerably both in a British and a Dutch population. In the British population, the interval between the two events has been maintained such that peak food abundance continues to coincide with the greatest food demand by the offspring and the population is thriving (Charmantier *et al.*, 2008). In the Dutch population, however, laying date and food peak have advanced at different rates. The increasing mismatch between both has resulted in a steady decline of reproductive success over the past 30 years and in measurable selection for increased plasticity. But while there is significant heritable variation in plasticity of laying date ($h^2 = 0.32$), there is as yet no evidence for a selection response (Nussey *et al.*, 2005). While the established reaction norm in the British population happens to fit the temperature trend over the past 30 years, there are apparently constraints on achieving a similar fit in the Dutch population despite available genetic variation.

Figure 1 Norms of reaction. Shown are the norms of reaction for a given trait and for two genotypes, 1 and 2, along an environmental gradient. (a) The genotypes differ in the overall trait mean but are equally plastic, as indicated by the identical slopes of their reaction norms. (b) Genotype 1 not only expresses larger trait values overall but also shows greater plasticity than genotype 2.

Phenotypic Plasticity versus Microevolutionary Change

In any analysis of phenotypic change following an environmental perturbation or a colonization event, phenotypic plasticity is the obvious alternate hypothesis to adaptive microevolutionary change and needs to be evaluated. This holds even for traits that are not generally thought of as being responsive to environmental conditions. The experimental introductions of *Anolis sagrei* lizards to 14 small islands in the Bahamas from a nearby source population are a case in point (Losos *et al.*, 1997). The shorter vegetation on the islands was predicted to select for relatively shorter hindlimbs, because these allow for greater agility on narrower perches. Within 14 years after the introduction, exactly this pattern was observed, which is also manifest more broadly in intra and interspecific comparisons in the spectacular radiation of Caribbean *Anolis* species. Phenotypic plasticity most likely played a role in the island introductions, because in a separate study the lizards were shown to vary in their relative hindlimb length depending on the kinds of perches on which they had been raised (Losos *et al.*, 2000). Note that genetic drift may

also be responsible for phenotypic changes especially when population numbers have been severely reduced following an introduction, a range of expansion or an environmental perturbation. However in that case, one does not expect a correlation between ecological parameters and the direction of phenotypic change.

The role of plasticity in adapting organisms to novel habitats has been viewed from two different perspectives: either as a source of phenotypic novelty that may be subsequently fixed by the genetic system ("genes as followers," West-Eberhard, 2003) or as an evolved, genetically codified strategy that is subject to modification by natural selection ("genes as leaders," de Jong, 2005). In the latter case, plasticity is expected to aid the colonization of a novel environment if conditions there resemble those that have been previously experienced and have thus shaped the plastic response (Ghalambor *et al.*, 2007). Price *et al.* (2003) suggested that an intermediate level of plasticity is optimal, because it allows the organisms to persist in a new habitat while still offering scope for genetic adaptation. Tests of these hypotheses would allow for predictions of the success of invasive species and the persistence of established populations at a time of global change.

Local Adaptation versus Gene Flow

"Site-Specific" Adaptation is Common

Environmental heterogeneity that is coarse grained and mostly spatial rather than temporal favors genetically based local adaptation over costly phenotypic plasticity (Kawecki and Ebert, 2004). For a given habitat, local adaptation is defined as a higher fitness of resident as opposed to immigrant genotypes. A recent survey of reciprocal translocation experiments showed that this condition was fulfilled in 65% of all cases (Hereford, 2009). In 29% of the studies, however, immigrants had a higher fitness than residents, which suggests that there are impediments to the spread of locally beneficial alleles that have arisen elsewhere. Hereford (2009) also found evidence for trade-offs in 49% of all cases such that a given genotype had a fitness advantage in its own but a fitness disadvantage in the alternate habitat. This analysis underscores the frequent occurrence of "site-specific" adaptation, but does not take the distance between the experimental sites into account. Therefore, it does not address the tension between selection and gene flow that limits local adaptation on small spatial scales. The following is an overview of the theory on this issue.

Population Genetic Models

In the case of strictly spatial heterogeneity, the critical conditions for local adaptation can be illustrated with a simple deterministic model of two populations of constant and equal sizes in which alternate alleles at a single locus are selectively favored (see Lenormand, 2002 for a more detailed presentation of the theory). Local adaptation in this model is equivalent to the persistence of both alleles at equilibrium.

Without gene flow, only the local fitnesses determine the equilibrium conditions and each allele will be fixed in the population in which it is favored. At the other end of the spectrum, imagine that in every generation all offspring are thoroughly mixed and then each randomly assigned to one or the other population. In this case, only the mean fitnesses across both populations matter. Both alleles will then persist, if their mean fitnesses are exactly identical (Levene, 1953). For even slight differences in mean fitness, local adaptation is impossible unless genetic exchange is limited: the gene flow rate m (i.e., the proportion of each population that is replaced by immigrants per generation) must lie below a threshold that is determined by the strength of local selection in each population (Bulmer, 1972).

For example, if one allele has a local fitness advantage in its "own" population of 5% but a mean fitness disadvantage of 2.5%, then m must be smaller than 0.05 in order for it to be maintained at equilibrium. For $m \geq 0.05$, mean fitness "wins" over local fitness and the allele will be lost. The maximum permissible m becomes even smaller as the mean fitness disadvantage increases. Conversely for a given set of mean fitnesses, local adaptation can only be sustained in the presence of more gene flow if local selection is proportionately stronger. Finally, if the conditions for local adaptation are met, then the regular influx of the other, maladapted allele causes the population mean in each population to deviate from the local optimum. This deviation is called the migration load.

This model can be extended to populations of unequal size. Mean fitness is then weighted by population size, because it reflects the average selective regime experienced by individuals. Consequently, the allele that is favored in the smaller population has a reduced mean fitness and the conditions for its persistence become more stringent. Local adaptation to environmental conditions that are rarely encountered, for example, at the edge of a species range, is thus harder to achieve.

Another set of models takes the spatial scale of dispersal and of selective regimes explicitly into account. In these models, individuals are continuously distributed in space. Dispersal is quantified in terms of the mean distance that an individual travels between birth and reproduction (σ). Assuming a sharp ecotone, that separates two different, infinitely large habitats, and two differently adapted alleles at a single locus (as above), one expects at equilibrium a clinal change of allele frequencies across the ecotone and fixation of the locally favored allele on either side. The width of the cline is proportional to the characteristic length $\sigma/\sqrt{s}$ (Slatkin, 1973), where s is the selective advantage of the locally favored allele. Weak selection and wide-ranging dispersal thus widen the area in which the maladapted allele persists and imposes a migration load. The characteristic length also determines whether a locally adapted allele can be maintained in an "environmental pocket" that is embedded in a larger region in which the alternate allele is favored. For all but the strongest selection pressures, the minimum size of the pocket must extend over several to many dispersal distances (Slatkin, 1973).

The analysis of quantitative traits at an ecotone is more complicated in part because the mixing of differently adapted

populations generates statistical associations among alleles at different loci (so-called linkage disequilibria) which violate the assumptions of the quantitative genetic model. However, based on a number of approximations, it could be shown that the trait mean should vary on a scale of $\sigma/\sqrt{2sV_A}$ (Slatkin, 1978, Barton, 1999) and so should be able to track the environment quite closely. Spichtig and Kawecki (2004) simulated clines in polygenic traits at an ecotone and found that local adaptation was favored by strong selection for the locally adapted phenotype and by moderate selection against intermediate phenotypes. If intermediates were selected too strongly, then a locally adapted population could not become established, whereas weak selection allowed generalist intermediates to outcompete the locally adapted specialists.

Empirical Studies

There are a number of clear illustrations how gene flow can reduce the degree of local adaptation. For example, the optimal egg-laying dates of blue tits (*Parus caeruleus*) along the Mediterranean coast differ between deciduous and evergreen forest by about a month. On the French mainland, frequent gene flow from the predominant deciduous forest into smaller patches of evergreen forest caused a mismatch between laying date and bud burst in the latter (Dias and Blondel, 1996). On the island of Corsica however, gene flow rates are demonstrably much lower such that blue tit populations in deciduous forest (the minority habitat there) were well adapted and strongly genetically differentiated from nearby populations in evergreen forest (Blondel *et al.*, 1999). Negative correlations between estimated gene flow rates and adaptive phenotypic divergence among nearby populations were found in stream-side salamanders (*Ambystoma barbouri*, Storfer and Sih, 1998) and threespine sticklebacks (*Gasterosteus aculeatus*, Hendry and Taylor, 2004). A long-term study of local selection on a suite of behavioral traits in the spider *Agelenopsis aperta* documented in detail how selection acted on immigrants and their offspring. It also included theoretical modeling to define the phenotypic optima and to predict how quickly these would be reached if gene flow ceased (Riechert, 1993; Riechert *et al.*, 2001).

Gene Flow Can Promote Local Adaptation

Gene flow need not be an antagonist to adaptation. Most importantly, it spreads universally favored mutations across a species range (for a review see Morjan and Rieseberg, 2004). It can also aid local adaptation by supplying new alleles to populations with limited genetic variance. This can facilitate adaptation at the edge of a species range (see Geber, 2011 and associated papers) or after a drastic reduction in population size. The coevolution between parasites and hosts represents another evolutionary process in constant need of new genetic variation.

The theoretical prediction that gene flow can facilitate local adaptation in such systems (Gandon, 2002) has been experimentally tested with bacterial hosts and bacteriophage “parasitoids.” Experimental evolution in microbes allows for the study of large, replicated populations over many generations and for the direct comparisons of genotypes across time

(i.e., from frozen stocks). In the present context, it also enables the experimenter to control a suite of key parameters that would be difficult to measure let alone manipulate in nature. Compared to a set-up without gene flow, regular genetic exchange between replicate microcosms of bacteria and phage increased both the overall occurrence and the spatio-temporal variability of local adaptation in the phage (Forde *et al.*, 2004). The latter observation might explain why snapshots of unmanipulated host–parasite systems in nature give overall inconsistent results with regard to local adaptation. In another study (Morgan *et al.*, 2005), host and parasitoid gene flow rates were manipulated independently (either host or parasitoid or no gene flow). As before, parasitoid gene flow led to increased local adaptation in parasitoids. In addition, there was evidence at the end of the experiment that parasitoid gene flow had increased parasitoid adaptation to nonlocal hosts, which could reflect the spread of universally favored alleles. Interestingly, host gene flow had no effect on the level of local adaptation in the host.

Genetic Basis of Ecological Variants

Quantitative Trait Locus (QTL) Mapping

Methodological developments over the past 20 years have provided insights into the genetic basis of quantitative trait variation that had so far been hidden inside the “black box” of quantitative genetics. The development of abundant genetic markers, linkage maps, and statistical methodology has led to new, sophisticated implementations of an old idea (Sax, 1923): the approximate genomic locations and effect sizes of genes underlying a trait can be identified through statistical associations between trait values and marker genotypes (Mackay, 2001; Mauricio, 2001). The typical design involves a cross between individuals from genetically and (usually) phenotypically divergent selection lines or populations for which a linkage map of genetic markers exist. The largely heterozygous F1 generation is then further crossed to generate sets of recombinant offspring (F2 or backcross) in which significant cosegregation of a trait with alleles at a particular marker locus identifies a “quantitative trait locus” (QTL) that is closely linked to the marker. In reality, a QTL may represent more than one linked locus influencing the trait. More recently, additional statistical methods have been developed to map QTL in outbred populations including pedigreed populations in the wild (Slate *et al.*, 2010).

Test of the Quantitative Genetic Model

Quite often, such studies have detected a few loci of large effect and a relatively large number of small effects for a given trait. In addition, there are numerous examples of dominance and of epistatic interactions (Roff, 2007). At face value, these data contradict the assumptions on which the quantitative genetics model is built (cf. Box 1). However, several considerations narrow the apparent gap between theory and data. Hill *et al.* (2008) emphasized that significant nonadditive allelic interactions in test crosses do not necessarily imply substantial nonadditive genetic

variance at the population level, because the latter depends on allele frequencies. For loci underlying QTL, these are expected to have U-shaped distributions (i.e., most alleles have frequencies either near 0 or near 1) in the case of neutrality and under various selective regimes. This implies that most nonadditive allelic effects would mainly contribute additive genetic variance to the trait. Furthermore, if the commonly observed epistatic QTL effects are largely contingent on the particular subset of alleles that is present in test crosses, then some large additive effects of “major loci” may similarly disappear if the alleles in question were randomized across genetic backgrounds in the population (Roff, 2007). In addition, the small sample sizes used especially in early QTL studies ($N \approx 200$) led to a systematic underestimation of QTL numbers and overestimation of their effects (Beavis, 1998). Finally, traits based on structural loci of large effect may still have normal genotypic and phenotypic distributions if regulatory genes generate a continuous distribution of expression levels (Roelofs *et al.*, 2006). Thus, while loci of large effect clearly do contribute to continuous trait variation in natural populations and, indeed, are expected to play an important role in the adaptive process (see The Genetics of Adaptation), currently available QTL data most probably overestimate their frequency and, on balance, do not amount to a refutation of the quantitative genetics model.

The Genetics of Adaptation

The distribution of allelic effects underlying a trait depends in part on the strength of directional selection acting on it. This is dramatically illustrated by the adaptive responses to strong anthropogenic selection, for example, via insecticides, warfarin or heavy metal contamination of mine sites. Resistance in these cases is overwhelmingly based on no more than three loci and mostly just one locus (Macnair, 1993; French-Constant *et al.*, 2004). In fact, a gradual process based on genes of small effect is not an option here, given that a) the new optimum lies decidedly outside the initial distribution of phenotypes and b) survival requires a considerable level of resistance from the outset (Macnair, 1991). For example, the establishment of grasses on contaminated mine sites depended on the presence of the tolerance allele at low frequency in the surrounding population. None of the species that grew nearby but lacked such pre-existing alleles have succeeded in colonizing the mine sites (Bradshaw, 1991). More generally, theory predicts that adaptation to a new phenotypic optimum consists of a sequence of allelic substitutions of diminishing effect size. The typical finding in QTL studies of few “large” and many “small” loci agrees qualitatively with this prediction, as does the observation in microbial studies that alleles of large effect are fixed early in the adaptive process (for a review see Orr, 2005).

Insights from the Genes Underlying Adaptation

There is usually a long way to go from the identification of a QTL to the discovery of the gene(s) that actually produce the phenotypic effect. However, once identified, they offer new

insights that can go beyond the scope of ecological genetics and so provide a much broader context to the field study. The following examples illustrate, respectively, a molecular mechanism of heterozygote advantage, contrasting pleiotropy per locus versus per trait and the phylogenetic origin of an adaptation.

In *Colias* butterflies, phosphoglucose isomerase (Pgi) is a key enzyme involved in the energy supply to flight muscles. In both *Colias eurytheme* and *Colias meadii*, two common alleles persist at intermediate frequencies due to heterozygote advantage in terms of enzyme kinetics, flight ability, and fitness (including male mating success and female survival; Watt *et al.*, 1983). The underlying mechanism of this effect has been explored at the level of enzyme structure in *Co. eurytheme* (Wheat *et al.*, 2006). In this dimeric enzyme, heterozygote advantage appears to originate from the heterodimer's flexible conformation that allows enzyme performance to alternate between maximizing substrate binding strength and processivity. Under this hypothesis, the heterozygote can resolve a trade-off that limits the performance of either homozygote.

Following the last ice age, many independent colonizations of Canadian freshwater lakes by marine threespine sticklebacks (*Ga. aculeatus*) have prompted parallel changes in a whole suite of traits. While QTL studies have found most of these to be polygenic, one trait, the number of pelvic plates, is clearly associated with a major locus, ectodysplasin (*Eda*, Albert *et al.*, 2008). The high-armored morph of marine populations is thought to protect against fish predation. In lakes, the low-armored allele has become established in most cases. Laboratory and artificial pond experiments that mimicked the freshwater habitat, led to a significant increase in its frequency and it conferred a growth advantage to very young fish, which should reduce mortality due to invertebrate predation (Barrett *et al.*, 2008). However, an initial, substantial frequency decline of the low-armored allele in the ponds (and only there) as well as apparent heterozygote disadvantage in a natural polymorphic lake population indicate that selection at this locus is considerably more complicated (Schluter *et al.*, 2010). Similarly complex antagonistic selection due to pleiotropy or closely linked genes was also discovered for a flower-color locus in the morning glory (*Ipomoea purpurea*, Coberly and Rausher, 2008) and for a coat-color locus in a wild sheep population (Gratten *et al.*, 2008).

Finally, phylogenetic analyses of genes linked to several QTL have provided important new insights into the rapid evolution of a new host race in the apple maggot fly (*Rhagoletis pomonella*) in North America. In this classic example of sympatric differentiation, development of the larvae on apple (the new host) as opposed to hawthorn requires a different timing of winter diapause. The genes underlying this trait map only to three chromosomal regions all of which are located in inversions (Feder *et al.*, 2003). This genetic architecture greatly facilitates sympatric differentiation, because the inverted regions do not recombine with the “wildtype” homologs. Moreover, molecular phylogenies of genes within these inversions suggest that the flies' response to disruptive selection since the introduction of apples about 150 years ago made use of an existing diapause syndrome that is 1.5 million years old (Feder *et al.*, 2003).

Eco-Evolutionary Dynamics

From Populations to Communities and Ecosystems

Phenotypic change due to microevolutionary processes such as adaptation to a new resource, more efficient exploitation of an old one or the acquisition of resistance to a pathogen is likely to effect the abundance of the evolving species. Changes in density commonly alter the optimal strategies of growth and reproduction, which might trigger further adaptive responses. This “quintessential link” between selection response and numerical abundance can generate an “ecogenetic feedback loop” in the target species (Kokko and López-Sepulcre, 2007). It may also have profound effects on other species with which it interacts. There may be “ripple effects” (Thompson, 1998) throughout a biological community that could range in principle from the exclusion of a competitor to changes in food web structure or in patterns of nutrient cycling. Alternatively, concurrent subtle microevolutionary changes in more than one interacting species may not immediately alter the structure of a community but affect its stability (Jones *et al.*, 2009). Thompson (1998, p. 331) argued that “to dismiss or ignore these rapid, fluctuating evolutionary processes as trivial evolutionary meanderings... is to miss the real interface of evolution and ecology in community dynamics.” The increase in successful demonstrations of adaptive microevolution in single species has led to a recent surge of interest in these community effects (e.g., Neuhauser *et al.*, 2003; Hairston *et al.*, 2005; Fussmann *et al.*, 2007; Kokko and López-Sepulcre, 2007; Pelletier *et al.*, 2009 and associated papers).

The ecogenetic feedback loop focuses on single species: it is closed when adaptive change in a population leads to a change in population density which, in turn, causes variation in reproductive success among individuals based on some aspect of their phenotype (Kokko and López-Sepulcre, 2007). Eco-evolutionary dynamics are more broadly defined (Pelletier *et al.*, 2009; Post and Palkovacs, 2009). They comprise the unidirectional links from evolution to ecology and vice versa as well as bidirectional interactions. The link from evolution to ecology may consist of demographic change in one or more species, adaptive responses in interacting species, changes in community structure or stability or changes in ecosystem processes. The link in the opposite direction can affect not just mean phenotypes but also the levels of heritable genetic variation and the spatial distribution of genetic variation across landscapes of fragmented and potentially heterogeneous habitats (see Zheng *et al.*, 2009 for an example). Strong links are expected between strongly interacting species, whereas effects are expected to diminish as one moves from pairwise interactions to whole communities and to ecosystems (Pelletier *et al.*, 2009). Since antagonistic pairwise species interactions, for example, between hosts and pathogens can be both strong and persistent, they have long featured prominently in eco-evolutionary studies (e.g., Dwyer *et al.*, 1990; Thrall and Burdon, 2003).

Demonstrating a complete feedback poses a formidable challenge especially in natural populations (Kokko and López-Sepulcre, 2007). A large amount of high-resolution data is required to establish the causal links between concurrent changes. Once a system has settled at a new equilibrium,

it will often be impossible to reconstruct these in hindsight. In addition, the strength of the interaction may vary locally. For example, a third species that weakens the link between two primary contestants may occur in some places but not in others. According to the geographic mosaic theory of coevolution (Thompson, 2005), spatially variable conditions across sites mean that reciprocal evolutionary change will occur in some sites (“coevolutionary hot spots”) but not others and may subsequently spread to other populations.

The analysis of eco-evolutionary dynamics typically requires a combination of observational data, experimental studies, and the analysis of theoretical models. A rich theoretical literature has accumulated over the past 40 years (reviewed in Fussmann *et al.*, 2007; Kokko and López-Sepulcre, 2007) that provides inspiration for the analysis of any particular eco-evolutionary study system. Theoretical models feature in all of the following three examples.

Case Studies

Populations of *Daphnia dentifera*, a cyclical parthenogen, are subject to episodic outbreaks of infection with a yeast parasite (*Metschnikowia*), which severely reduces fitness and ultimately kills the host. Duffy and Sivers-Becker (2007) found that the susceptibility to infection in *Da. dentifera* clones from populations with a recent parasite outbreak was lower on average and also less variable compared to lake populations that had not experienced a recent epidemic. The authors therefore included clonal selection by the parasite into a model of this species interaction and incorporated field estimates of all key parameters. The model generated correct predictions of outbreak duration and host population size during an outbreak only in the case of a genetically variable host population. Particularly, outbreaks came to a definite end in nature and in this version of the model, whereas they persisted endemically in models of genetically uniform hosts. Thus, eco-evolutionary dynamics may be able to resolve a commonly observed discrepancy between theory and data that has puzzled epidemiologists for some time.

The Soay sheep population on St. Kilda undergoes frequent fluctuations in abundance. Population crashes have been caused by a combination of high densities and adverse weather conditions (mild winters and heavy spring rains), but different age groups of each sex were differently affected by these conditions. For a given weather regime and total population size, the population growth trajectory will therefore be affected by the current age structure (Coulson *et al.*, 2001). Moreover, for several sex/age subgroups within the population, the patterns of survival and reproduction were nonrandom with regard to body size (Pelletier *et al.*, 2007). The strength of natural selection on body size was considerably greater in crash years as opposed to noncrash years. Pelletier and coworkers traced the effect of natural selection on body size via survival during and reproduction following a crash all the way to the level of additive genetic variance for that trait.

Finally, in a chemostat experiment of a copepod predator (*Brachionus calyciflorus*) and its algal prey (*Chlorella vulgaris*),

evolutionary processes had to be invoked to explain the observed population cycles (Yoshida *et al.*, 2003). The results from initial experiments had been incompatible with standard models: the observed predator and prey cycles had periods that were too long and population maxima that were too strongly offset relative to each other. However, agreement with the theory was achieved when only a single algal clone was used in the chemostat. Separate selection experiments established the existence of genetic trade-off among *Chlorella* clones between reduced nutritious value (a defense against the predator) and competitive ability, which were favored in the presence and in the absence of *Brachionus*, respectively. When clonal diversity reflecting this trade-off was incorporated into the model, it correctly predicted the length and phase relationship of the observed cycles. Moreover, when the relative frequencies of two well-characterized algal clones were directly monitored, the chemostat dynamics were indeed attributable to clonal selection as predicted by the trade-off (Meyer *et al.*, 2006).

Conceptual Developments

The recent empirical advances in the study of eco-evolutionary dynamics have been paralleled by a number of conceptual developments. Hairston *et al.* (2005) have argued that the rate of evolutionary change per time is not a good metric with which to determine whether evolution has operated “rapidly,” i.e., on an ecological time scale. This is partly because published rates tend to vary inversely with the length of the measurement interval and because they are uninformative unless they are viewed in the context of a concurrent ecological process. Hairston *et al.* (2005, p. 1117) propose that “evolution is rapid... only if the heritable phenotypic change occurs sufficiently quickly to alter the trajectory of an ecological process while it is still in progress.” They further propose a method to partition the rate of change in an ecological variable of interest into components due to evolutionary and ecological causes. The relative contribution from evolutionary change can thus be objectively determined.

The joint consideration of evolution and demography departs from traditional evolutionary analyses which model variation in fitness among genotypes or phenotypes as their relative per-capita contributions to the next generation such that the mean fitness is one (Saccheri and Hanski, 2006). In other words, the population size is assumed to be constant and also large enough so that stochastic effects can be ignored. In an eco-evolutionary context, population size and its change over time are products of the absolute rates of survival and reproduction of individuals (Antonovics, 1976). To explore how individual variation affects population growth in this context, Coulson *et al.* (2006) suggested a theoretical framework that captures the entire process from the action of individual genes to the rate of population increase (or decrease) through a hierarchy of three “maps”: genotype → phenotype, phenotype → demography, demography → population growth. The mechanistic or statistical mapping rules determine how sensitive variation at one level is to perturbations at the level below. The framework is intended for theoretical exploration and, in particular, as a tool to identify levels

of detail that can be justifiably suppressed in a given situation.

Outlook

The interface between ecology and genetics has long been considered to be a source of important insight for both “parent disciplines.” But for a long time, the field was represented by a collection of intriguing case studies with diverse conceptual affiliations. Emboldened by the success of earlier pioneering studies and equipped with new tools for data collection and analysis, researchers have since brought ecological genetics into focus as an integrated discipline. Patterns have emerged from the wealth of accumulated information and these have led to new questions. A selection based on this article is summarized here.

Why do we often not see a selection response when it is predicted from the breeder’s equation? What are the relative contributions of fluctuating selection, counter-gradient selection, environmental trait/fitness covariance and genetic correlations (Merilä *et al.*, 2001) to the solution of this puzzle? Answers to these questions should help to clarify how natural selection in the wild differs from selection experiments in the lab and how organismal integration affects the true amount of genetic variation on which selection can act. Such answers should also shed light on two important evolutionary issues: the maintenance of genetic variation and the question to what extent microevolutionary processes determine macroevolutionary patterns. Finally, we need to understand to what extent microevolutionary potential and phenotypic plasticity reduce the risk of extinction due to global change.

What are the critical factors that determine whether a given species’ ongoing adaptive change triggers eco-evolutionary dynamics? It is worth considering that two of the three case studies (cf. Eco-Evolutionary Dynamics) involved adaptation by clonal selection in strong pairwise species interactions, i.e., under conditions that are most favorable for eco-evolutionary dynamics. In the Soay sheep, the selection strengths varied significantly with density but were small in absolute value. The potential implications of constantly evolving species for community organization and stability are profound, but at present it is not known what proportion of microevolutionary change simply dissipates without any knock-on effects.

Methodological advances will help to generate the high-resolution data sets with which to address these questions, especially as dense linkage maps become available even for nonmodel species. These maps allow, for example, for direct estimation of relatedness without a pedigree. Adaptation can be monitored at the molecular level by mapping QTLs for a trait and then following allele frequency changes at linked marker loci in nature. Moreover, breeding values can be estimated from such marker data so that microevolution can be distinguished from purely phenotypic change that is driven by environmental trends (Kruuk *et al.*, 2008).

Finally, progress depends as ever on painstaking and long-term field research. Even in the age of high-throughput DNA sequencing and genotyping, the importance of monitoring carefully selected environmental variables in the “messy” real

world and of knowing the natural history of the study organism is undiminished (Rausher, 2005, Conner, 2010).

Glossary

Accession Usually a sample (e.g., seed lot) but may be a set of genetically related samples.

Collection One or more accessions.

Gene pool The genetic diversity contained within a population, species, or crop. The primary gene pool of a crop represents the biological species, the secondary gene pool includes species that can be crossed with it, allowing at least some transfer of genes, and the tertiary gene pool

includes related wild species where such gene transfer involves specialized techniques.

Genotype The genetic makeup of an individual.

Seed lot A sample of seeds with a common harvest and post-harvest history.

Wild or nondomesticated species Those species that have not been brought into regular cultivation. Many may, however, have well-known uses.

A gene bank is an *ex situ* (or offsite) collection of genetic material held for long-term security or for ease of access. The genetic material is usually in the form of live propagules or gametes though, increasingly, pure DNA is held. A bank can also be a collection of full-grown plants representing the diversity of certain species (a field gene bank) or a set of cultures (cell, tissue, embryo, or microorganism). The widest definition might also embrace collections of plants grown primarily for purposes of education and horticulture in botanic gardens and animals represented in zoological gardens or parks.

Role Within Conservation Strategies

Ex situ (or off site) conservation underwrites conservation measures *in situ* (on site or in the natural state) and provides centers from which genetic material (germplasm) can be accessed for research, breeding, or (re-) introduction. Nearly any *ex situ* collection might be included under the loose definition of a “gene bank.” As with a financial bank, deposits are made with the intention of later withdrawal. Furthermore, while in the gene bank, safety and integrity will be paramount and value will be added through study. However, the emphasis placed on withdrawal varies considerably between gene banks. For some collections, short-term utilization is the sole motivation, though inevitably conservation will be served to some extent. In others, long-term insurance against loss *in situ* is the stronger driving force. Given the increasing risks of genetic erosion (i.e., a narrowing of the gene pool leading to species being condemned to extinction) as a result of human

development pressures and the not inconsiderable difficulties of managing *in situ* populations, the likelihood is that many such collections will be called on in the future.

While *in situ* conservation should be seen as the primary goal of all conservationists, having a second line of defense is a prudent measure particularly if it assists in other ways. For example, by acting as a supply source, *ex situ* collections reduce the pressure of repeated sampling of wild populations. Importantly, through the use of such collections, access to national genetic resources can also be controlled. Furthermore, because research is facilitated by such collections, knowledge about both the conservation biology and socioeconomic value of wild populations is improved, thereby increasing the likelihood of survival *in situ*. It is sometimes asserted that *ex situ* conservation of certain species reduces political will to conserve the habitats in which they occur. Should this be true, it would seem essential to ensure against the loss of, at the very least, flagship species within the habitats so that they can be reintroduced. Additionally, it should be apparent that habitat complexity may limit reconstruction opportunities from *ex situ* collections. In summary and as often stated, *ex situ* conservation is complementary to that carried out *in situ* (see also the entry for “*Ex situ, in situ* conservation”).

The main types of animal *ex situ* collections are zoological gardens and parks, sperm and ova banks, and DNA banks. Due to controlled breeding programs, genetic resource databanks also play a more prominent role in the management of such collections than is perhaps the case with those for plants and particularly those in botanical garden collections. Microbe collections are mainly cultures though the possibility exists for fungal spore banks.

When considering plant species, the main types of *ex situ* collections are botanic gardens specimen collections (each normally comprising many species and few individuals per species); field gene banks (usually few species, many individuals); seed, pollen, and spore gene banks (potentially many species, many individuals); *in vitro* cultures (relatively few species, many individuals); and DNA banks (potentially many species, many individuals—though the latter are rarely held separately). The collections vary in the degree of technical input required, their ability to effectively conserve inter- and intraspecific variation, their longevity, and the ease with which gene products can be obtained. Seed gene banks (in this entry abbreviated to “seed banks”) nicely balance these factors and offer a very effective form of *ex situ* conservation for many plant species. For this reason and the fact that most references to gene banks relate to seed banks, this chapter will firstly consider this type of gene banking and in particular the technology.

Seed Banks

Seed Banks are an Effective Form of *Ex Situ* Conservation

What makes seed banks such an effective *ex situ* conservation technique is that the methodology can be applied to a wide range of species in a universal and straightforward way and that large amounts of intraspecific diversity can be conserved and for long periods of time without intervention.

The fecundity of most plants means that a small seed sample can be removed from the annual seed rain with limited effect either on that population's survival or on the seed yield. One seed lot, if carefully sampled, can hold the majority of alleles found within that population. Moreover, if carefully germinated and then grown up under the same conditions, a seed lot has the potential to recreate the original population. In the meantime it can be held within a relatively small volume. For instance, a million tobacco seeds, each one with the potential to grow into a genetically distinct plant, occupy about a fifth of a liter.

Additionally, germinating seeds to obtain fully grown plants is relatively simple compared with obtaining plants from *in vitro* stored material. Plants recovered from banked seeds can also be compared with natural populations from which the material was harvested years before and which may have been subjected subsequently to environmental change (e.g., as a result of global warming).

The Historical Context

Seed banks might be seen as an invention of the 20th century, though the exploitation of crop seeds' ability to store in a dry state has almost certainly played a significant role in early human civilization. Early forms of seed storage probably included burying the seeds in ash or sealing them in adobe huts for the following season. By comparison, modern seed banks use controlled drying facilities and deep freeze stores and aim for storage lives of decades, centuries, or more. Modern seed banks have a lineage built on plant exploration and the development of botanic gardens that dates back nearly 5 millennia.

A collection of medicinal plants was established in China in 2800 B.C. Three hundred years later, the Sumarians were collecting vine germplasm from Asia Minor. During the Middle Ages, the Islamic world made great strides forward in the study of plants and their properties. There followed a proliferation of gardens of medicinal plants during the late Middle Ages and Renaissance of Europe. Acquisition and exchange of crop plants gathered pace with the colonial activities of the European powers. For instance, Columbus took wheat and other seeds to the New World (Plucknett *et al.*, 1987). Following such relocation of crops and their subsequent adaptation and diversification, the current patterns of food species use were established. Current collections of crop genetic resources reflect a strong degree of interdependence across the world on genetic diversity born out of this era of colonization. For example, one study suggests that North America now relies nearly totally on, and two-thirds of developing countries now obtain more than 50% of their crop production from, crops domesticated external to their region (FAO, 1996).

European colonization spurred on the development of many of the world's botanic gardens. For instance, the French established the first tropical botanic garden at Pamplemousses in 1735 to act as a staging post for germplasm movement and to screen for use. The Royal Botanic Gardens, Kew, was established in 1759 and in turn helped develop botanic gardens elsewhere in the world (e.g., Singapore). These subsequently acted as conduits for distribution of germplasm around the world. Many famous plant collectors date from this period of European colonial expansion and include Sir Joseph Banks, Richard Spruce, and George Forrest (see Plucknett *et al.*, 1987). Not surprisingly, many botanic gardens now hold important collections of both endemic and exotic nondomesticated species including those known to be used locally for medicines and timber plus many ornamentals.

Changed agricultural practice and increased pressure on the natural world during the 20th century has led to increased erosion of genetic diversity both in crops and wild species. Currently, the most important causes of genetic erosion are considered to be replacement of local varieties, land clearance (e.g., fuel-wood collection), and overexploitation; some of the greatest concern relates to diversity found in the arid and semiarid regions (FAO, 1996). In 1949 there were about 10 thousand wheat varieties in China; in the 1970s the number had reduced to a thousand. Erosion of the genetic base of crops is not new. For instance cultivated carrot color was infinitely more diverse in Medieval Europe than it is now. However, the rate of erosion has accelerated in the 20th century with the drive toward greater genetic uniformity of crop varieties. Some highly uniform varieties have been sown across huge areas. In 1983 a single variety was sown across two-thirds of the wheat fields in Bangladesh and the following year across nearly a third of all those in India. This uniformity has productivity advantages within agricultural systems but is not without risk. For instance, there was a severe shortfall in winter wheat production in the Soviet Union when a variety grown over 15 million ha did not have sufficient cold tolerance to survive the winter of 1972. Less dramatic was the abandonment in 1975 of all of the United Kingdom's white clover varieties due to susceptibility to the disease *Sclerotinia trifoliorum* (FAO, 1996).

The more modern uniform varieties have been selected from genetically heterogeneous old varieties and landraces (primitive varieties) that they have then displaced. Therein lies the conundrum. For these new varieties to be developed further they need to draw on the genetic diversity that they have displaced. Half of the production increases of the Green Revolution were brought about by the use of plant genetic resources for plant breeding.

The Current Status of Seed Banks for Food and Agriculture

Although the outstanding Russian genetic resource scientist Nikolai Vavilov had assembled a collection of 50,000 cereal and pulses during the 1920s and 1930s, which were maintained by an annual grow-out, the first impetus to develop modern seed banks occurred in the United States. Here it was noted in the late 1940s that less than 10% of 160,000 plant accessions in the national system since 1898 could still be found (Plucknett *et al.*, 1987). Following the establishment of U.S. regional genetic resource facilities to address this problem, the National Seed Storage Laboratory (NSSL) was established at Fort Collins, Colorado, in 1958. With about 360,000 accessions, it and the Institute of Crop Germplasm in Beijing with about 316,000 accessions are the world's largest seed banks.

A significant proportion of the accessions held in crop genetic resource collections (including seed banks) date from the 1960s onward when the extent of loss of diverse landraces was becoming apparent. Catalyzed by the Food and Agriculture Organization of the United Nations (FAO) and subsequently by the International Board for Plant Genetic Resources (IBPGR, now the International Plant Genetic Resources Institute, IPGRI), a great amount of crop genetic diversity was saved in the 1970s and 1980s through the organization of collecting missions. Not surprisingly, conservation efforts have concentrated on the 30 crop species that provide 95% of dietary energy or protein. Of these species, rice, wheat, and maize provide 26, 23, and 7%, respectively. Consequently, about 40% of the estimated 6 million accessions conserved in the 1308 national and regional collections are cereals (of which 14% are wheat). A further 15% are food legumes. Other foods such as roots/tubers, vegetables, and fruits each comprise less than 10% of the total. Because many of the species in the collections are harvested for their seeds, it is not surprising that most accessions (about 90%) are held within seed banks. The remainder are held *in vitro* or within field gene banks (see later). Of the accessions for which there are data, perhaps half are advanced cultivars or breeders' lines and a third are landraces and old cultivars. The tertiary (plus much of the secondary) gene pool within wild and weedy species comprise only 15% of the accessions (FAO, 1996). The narrow range of species is indicated by the fact that forages and forest species are considered to have minimal coverage. There is no good estimate of the number of wild species held under internationally acceptable gene bank conditions. There are probably more than 10,000 species, but almost certainly less than 20,000 species, held. The National Plant Germplasm System in the United States accounts for some 8720 species (see ten Kate and Laird, 1999). This should be set against a background of about a quarter of a million scientifically

described higher plants. Obviously, the *ex situ* conservation of wild plant diversity remains a major gap that needs to be filled within the genetic resource system.

The international institutes within the Consultative Group on International Agricultural Research (CGIAR) system account for 10% of the 6 million accessions. These institutes include the following (with number of accessions, most of which are held in seed banks, shown in brackets; see FAO, 1996):

- The Centro Internacional de Mejoramiento de Maíz y Trigo (CIMMYT) in Mexico (136,637)
- The International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) in India (110,478)
- The International Centre for Agricultural Research in the Dry Areas (ICARDA) in Syria (109,029)
- The International Rice Research Institute (IRRI) in the Philippines (80,646)
- The Centro Internacional de Agricultura Tropical (CIAT) in Colombia (70,940).

Just under half of the 6 million accessions are held in 12 national collections. To some degree this is a function of the early establishment of their genetic resource collections. The collections include those in Russia and the United States (noted earlier), Japan (established in 1966), Germany (1970), Canada (1970), and Brazil (1974). Of the 1308 national or regional collections currently noted by FAO (1996), only 397 within 75 countries are held in long- or medium-term seed banks. Medium-term storage might be assumed to be in the order of 10 or more years.

Whilst 496 collections are within Europe and 293 are within Asia, some areas of the world have very few such facilities. FAO (1996) noted that there is only one long-term store within the Caribbean and this is in Cuba. Relatively few of the collections covered by the FAO survey are held by private companies, though many breeders hold smaller working collections.

The remits for crop banks are very varied. Some cover wide ranges of the crops that are important at the national or regional level, others cover very specific material. For instance, facilities at Horticulture Research International in Wellesbourne (United Kingdom) and the Asian Vegetable Research and Development Centre (Taiwan) have remits for vegetable germplasm.

While the science and technology underpinning these seed banks is generally well founded (discussed later), problems such as unreliable electricity supply mean that only the nine CGIAR banks, those in 35 countries and four regional centers, meet international standards as established by FAO and IPGRI (1994). To some extent this problem is obviated by the high level of duplication within the world's 6 million accessions. It is estimated that perhaps 1 to 2 million of these are genetically unique.

The way in which seed bank and associated genetic resource work is organized both at a regional and national level varies considerably. In Europe, the European Cooperative Programme for Crop Genetic Resources (ECP/GR) works through crop networks to coordinate effort. In Southern Africa, work is coordinated through a network set up through the Southern Africa Development Corporation (SADC). At a

national level, in India, genetic resources activities are formally centered around the National Bureau for Plant Genetic Resources. Within the United Kingdom, genetic resources activities are less centralized with responsibility residing with a number of institutes and their respective ministries. Advice to government is provided through the U.K. Plant Genetic Resources Group, which draws members from all of the relevant organizations.

Seed Banks for Wild Species

Increasingly, botanic gardens are adopting seed banking technology. Although [FAO \(1996\)](#) note that 150 botanic gardens (about 10% of the world total) have seed banks, relatively few of these have embraced international standards (discussed later). Those that have include the ones at the Berry Botanic Garden, Oregon (United States), the National Botanic Garden of Belgium, the Royal Botanic Gardens, Kew (Wakehurst Place), and the network of seed banks within the Spanish botanic gardens (notably Cordoba). Most botanic garden seed banks were born out of a need to more effectively manage the annual seed exchange. However, many now concentrate on the conservation of undomesticated species and interspecific variation. Additionally, several banks not in botanic gardens concentrate on wild species. These include the Threatened Flora Seed Centre established by the Department of Conservation and Land Management in Western Australia, the forest tree seed banks (e.g., the National Tree Seed Programme in Tanzania), and the seed bank of the Universidad Politecnica de Madrid. The latter bank was established in 1966 to conserve Crucifers and species from around the Mediterranean. Together with the Royal Botanic Gardens, Kew Seed Bank that has concentrated on wild species from the world's drylands, it has helped pioneer the application of seed bank technology for the conservation of wild species. Faced with the acceleration in wild plant genetic erosion and extinction, the Kew Seed Bank has taken on the ambitious objective of facilitating the conservation of seed from 10% of the higher plant species by the year 2010. Termed the Millennium Seed Bank Project, the work is a collaborative exercise involving botanical organizations from around the world. One of the aims of the Project is to maximize the efficiency of the banking work through an active seed research and technology transfer program. Other than the NSSL at Fort Collins, the project will have one of the largest seed research groups associated directly with a seed bank. Certain other botanic gardens, such as that in Rio de Janeiro, also carry out seed research work applicable to seed banking.

Community Seed Banks

A valuable role in seed banking is played by nongovernmental organizations (NGOs) at the community level. There is an increasing use of community seed banks within the developing world that involve donation, storage (usually on a short-term basis), and use of seeds at the local level. Examples include a set of community seed banks set up in North Eastern Brazil. The Plant Genetic Research Centre in Ethiopia is an example of a national program integrating with a community-based system ([Heywood, 1995](#)). Seed Savers in the United

States and the Henry Doubleday Research Association in the United Kingdom are examples of NGOs active at the national level in the conservation of traditional vegetable varieties through their heritage seed libraries.

Collection Value

A financial value can be placed on biodiversity in one of two ways (see [FAO \(1996\)](#)):

- Direct value, or a willingness of the market to pay for it
- Indirect value, including its value as an insurance policy, the value to a product derived from the input of specific genetic material or the travel costs people would accept to collect it or to visit it for tourism

Obviously, there are other ways of considering the value of biodiversity such as its "service" value to biosystems and its value as a heritage to each human generation. However, debate has not surprisingly concentrated on its economic value and consequently the issue of access to the genetic wealth contained within seed banks is an increasingly controversial subject. Behind this debate is an attempt to reconcile the financial contribution of samples collected in one country to the economy of other countries. A fundamental concern that is often expressed is the degree of control over agricultural systems, particularly within the developing world, by multinational agrochemical/seed companies. Concern revolves around the use of the following:

- Uniform F1 hybrid varieties (where the seed, if harvested from the crop by the farmer, subsequently produces a heterogeneous crop of lower yield)
- Varieties that work best within systems when treated with certain agrochemicals
- The use of genetically modified organisms (GMOs)
- Plant breeders' rights and, increasingly, patents

Set against a backdrop of a \$15 billion estimated annual turnover for the seed industry in Organization for Economic Cooperation and Development (OECD) countries, the debate has polarized on an "Industrial North-Developing South" divide. This has led to a useful reassessment of the sharing of benefits, though inevitably there has been some over expectation of the value of individual germplasm collections. Undoubtedly, there are examples of large financial contributions to the commercial world from plant germplasm. The value of genes for high sugar content from *Lycopersicon chmielewskii* have been estimated to contribute \$5 to 8 million annually to the tomato industry (see [FAO, 1996](#)). However, it is worth bearing in mind that these are the exceptions to the rule. Relatively few advances in plant breeding have been spectacular and few have resulted from the incorporation of single genes. Most have occurred from the gradual improvement of characteristics governed by many genes (polygenic characters). Of course, advanced genetic manipulation techniques may change this picture and, indeed, may have an impact on the perceived value of traditional crop genetic resources.

In contrast to the seed industry, the pharmaceutical sector is estimated to be valued at \$235 billion ([FAO, 1996](#)). Included within this turnover are plant-derived drugs, many of

which relate back to plants collected from developing countries. However, large financial returns from plant-derived drugs are unusual because major breakthroughs in the identification of new bioactive compounds from plants are infrequent. It is true that 34 out of the top 150 prescription drugs in the United States have a plant-based origin. This aside, despite the estimated tens of thousands of species investigated in bio-prospecting programs, only 90 plant species have yielded 119 compounds considered to be important drugs (see [ten Kate and Laird, 1999](#)).

The debate has driven the establishment of agreements covering the access to and the sharing of benefits derived from plant genetic resources. Consequently, seed bank curation needs to accommodate not only national and international legislation but compliance with increasingly strict conditions attached to the material by the country or organization originally providing the material to the seed bank.

The Convention on Biological Diversity (CBD) came into force on December 29, 1993, following its opening for signature at the Rio Earth Summit in 1992. It has provided party governments with a framework within which access to genetic resources and the sharing of benefits arising from their utilization can be negotiated. Many countries have either developed, or are preparing national legislation to implement, access and benefit-sharing provisions of the CBD. Fundamental concepts that are often incorporated into national access legislation are as follows:

- The need to obtain *prior informed consent* for acquisition of genetic resources from the appropriate national authority
- The need to reach *mutually agreed terms*, which implies a negotiation leading to a form of bilateral material transfer agreement specifying the terms and conditions under which material is transferred

In addition to the provisions of the CBD and implementing legislation at the national or regional level, certain seed bank collections may fall within the ambit of the International Undertaking (IU) on Plant Genetic Resources for Food and Agriculture (PGRFA). This is currently being revised in order to establish a *multilateral* access and benefit-sharing system for PGRFA that is compatible with regimes established under the CBD. It also recognizes the contribution made by indigenous farmers, in particular, to the development of plant varieties.

Seed banks, particularly the larger ones such as those within the CGIAR system (discussed previously), have responded to the emerging legal framework on access to genetic resources and benefit-sharing by reviewing the terms under which they acquire genetic resources and supply them to third parties. In many cases, seed banks have adopted the use of standard material transfer agreements that entitle the providing organization (or the country of origin of the material) to a share of any benefits arising from the utilization of the material. They may also restrict the subsequent transfer and use of the material. A pioneering worldwide project by 16 botanic gardens, which like the agricultural seed banks have traditionally supplied genetic resources to a wide range of users, has also attempted to find broadly standard terms under which material may be transferred to third parties.

Particular challenges faced by seed banks include the following:

- The acquisition of new material on terms that enable its subsequent distribution and use, so far as possible, on a common basis
- The development of a supply policy flexible enough to ensure that terms and conditions of any bilateral agreement (e.g., with the country of origin) are met, while enabling plant genetic resources to be also made available for food and agriculture under any multilateral system to be adopted in the revised IU
- The development of procedures that enable curators to clearly identify whether a proposal to acquire or supply material should be dealt with on a multilateral or bilateral basis. For instance, due to the single source nature of many successful pharmaceutical “hits,” such work may fall into the latter category

Finally, it is important to note that the benefit of the annual investment in PGFRA conservation and utilization compared with its estimated total annual cost of \$1 billion ([FAO, 1996](#)) is considered to be very high. For this reason it is essential that the future operations of seed banks are not threatened by financial insecurity.

The Scientific Principles Underlying Seed Banking

Viable seeds of many species when maintained in a dry and cold state are capable of being germinated many years later. This capability means that the long-term *ex situ* conservation of many higher plants is a realistic possibility.

Seed Storage Conditions

The science of seed storage is not a new one and dates back, at least, to China in the 6th century. Advances in the quantification of seed longevity under different storage conditions were made in the second half of the 20th century through the work of Harrington in the United States and Ellis and Roberts in the United Kingdom (see review in [Hong, Jenkins, et al., 1998](#)). Critical factors that determine seed longevity are the seed's moisture content, temperature, and gaseous environment; its initial viability; and its genetic background. With respect to the latter, differences between species would appear to be much greater than those within. Genetics particularly influences the relationship between seed longevity and seed moisture content. Most species produce seeds that can be dried to low moisture contents (e.g., where less than 5% of the seeds' fresh weight is water) without loss of viability. The seeds of such species are termed “orthodox.” Furthermore, orthodox seed longevity increases in a predictable fashion as the moisture content is reduced. Within limits, there is a straight-line relationship of negative slope between longevity and seed moisture content (up to about 15 to 25%) when both are expressed on a logarithmic scale. More simply, Harrington's rule of thumb states that a 1% reduction in moisture content roughly doubles seed longevity. Ellis *et al.* in 1989 found that drying seeds below a certain moisture content (equating to that in equilibrium with air at about 11% relative humidity at room temperature) did not increase longevity in most species

studied. However, in a few species, a decrease in longevity was noted.

Temperature also has a predictable effect on seed longevity over the range -13°C to 90°C (Dickie *et al.*, 1990) such that there is a quadratic relationship between longevity on a logarithmic scale and temperature—although an Arrhenius relationship also fitted the data well. Importantly, the relative effect of temperature on the seed longevity of eight species was identical. In its simplest form, Harrington's rule of thumb states that a 5°C reduction in temperature doubles seed longevity.

In 1980, Ellis and Roberts developed a predictive model for orthodox seed storage that incorporated the determinants of longevity (except gaseous environment that has minimal effect at the low moisture contents over which the model is applicable). Based on acceleration of the aging process in seed lots by increasing their moisture content and temperature, the model allows extrapolation of longevity at cooler and drier conditions. For instance, rice seeds at 5% moisture content and -20°C (fairly typical seed bank conditions) have a theoretical potential to survive at least 1900 years (see Hong *et al.*, 1998). Such data lend weight to occasional press reports of the germination of seeds of great antiquity, many of which cannot be confirmed due to the lack of supporting archaeological evidence. Nonetheless, there is, for example, evidence of longevity greater than 100 years at room temperature for dry wheat seeds (Steiner and Ruckenbauer, 1995). The seed storage model indicates the independence of temperature and moisture content on longevity over a wide range of conditions (Ellis *et al.*, 1995). It has been suggested that this may not necessarily be the case, particularly at very low moisture contents (Vertucci and Roos, 1990). The model also appears to be influenced by developmental stage (Hay *et al.*, 1997). These deliberations do not, however, alter the current seed bank storage recommendations (details of which are given later).

Even if these longevity predictions prove to be unattainable for all species, they do imply that, for some at least, storage in seed banks may be sufficiently long to carry the current heritage of genetic material to new eras when other technologies will be available. Predicted longevity of this magnitude also imply that the amount of regeneration of seed stocks inherent in many gene bank programs currently may be more a function of preferred working practice (e.g., regular study of collections), or poor application of the technology, rather than a failure of the technology itself.

In a study of the seed storage behavior of 6700 species, Hong *et al.* (1998), found that 91% had orthodox (desiccation tolerant) seed. The remainder had either desiccation susceptible or "recalcitrant" seed or had characteristics intermediate between the recalcitrant and orthodox types. Also certain genera (e.g., *Acer*) contain both orthodox and recalcitrant species. There is little evidence, however, that individual species produce both orthodox and recalcitrant mature seeds. It should, though, be noted that orthodox seed passes through a desiccation susceptible phase during development. The true percentage of species with orthodox seed within the plant kingdom is probably significantly less than 91% as the sample was biased toward species in trade. Although recalcitrant seed behavior is loosely associated with long-lived perennial species producing large fleshy fruits, there is great uncertainty of

the number of wet tropical forest species producing such seeds. Seed storage behavior is usually assessed by quantifying the survival of seed lots of a species after drying to different moisture contents. A more rapid biochemical diagnosis of potential survival of drying is clearly of interest. Most recalcitrant seeds, including oaks and rubber, die below a value of about 40% moisture content. Because they need to be kept moist (and aerated) they have short life spans, generally of a few months, and are not suitable candidates for seed banking. Other forms of genetic conservation must be employed. The same is true for species, such as coffee, which produce "intermediate" seeds that cannot be dried much below about 10% moisture content. They also tend to be susceptible to storage at cold temperatures (-20 and 0°C). Work on other species, such as orchids, suggests the use of other subzero temperatures may be appropriate for the conservation of species sometimes included in this storage category (Pritchard *et al.*, 1999).

Genetic Considerations

The genetics of seed bank storage is an important issue. A criticism occasionally leveled at seed banks is that there is selection in storage. Selection can occur during collection through a biased sample (e.g., for early or late flowering genotypes). It can also occur when samples are grown out under conditions that differ dramatically from those where the seeds were harvested. There is, however, little evidence to show that, compared with, say, room conditions, the seed bank environment does other than slow down the (normally distributed) times for individuals to die. In other words there is no greater risk of selection out of any individual by the conditions applied than under natural conditions.

Another criticism is that seed lots in a seed bank are protected from evolutionary pressures that maintain fitness. The extent of this problem will depend on the generation time of the species involved and the severity of the selection pressures (at the site from which it was collected) during the time the seed lot was in storage. It might be argued that those species with short generation times will quickly adapt to all but the most extremely changed environments (i.e., the gene frequencies in the seed lot will quickly be selected to meet the new needs). Of course, maintaining the original genes sampled from within the population may have longerterm benefits of fitness for the species if pathogen attack has altered the natural population in the intervening period. An additional consideration is the prospect of genetic contamination of natural populations by chance hybridization with exotic material including genetically modified organisms. This concern is also partially alleviated by the existence of long-term stored germplasm in its original state.

Seed Bank Management

Procedure

The basic elements of the seed banking procedure (more or less in order) are as follows:

- Collection planning and permission seeking
- Seed (and pressed specimen) collecting and field data recording

- Shipment of the seeds
- Creation of a data record about the accession
- Seed cleaning (sometimes preceded by initial drying and sometimes accompanied by X-ray analysis and quantity determination)
- Main drying
- Seed moisture determination
- Initial germination test (sometimes left until after banking)
- Packaging and banking and security duplication
- Characterization (including verification of identity in the case of wild species) and evaluation (where appropriate)
- Distribution of stocks to users (through time)
- Germination retests (through time)
- Regeneration/multiplication (as required)

Although many of the well-established seed banks broadly follow these procedures, most modify them to meet their own specific needs. Some banks carry out very little field collecting and some multiply the seed sample on arrival. Costs for each stage vary considerably between seed banks. The RBG Kew Seed Bank, which has an international collecting program, estimated, in 1997, that the ratio of costs between collecting, processing, and annual maintenance for a collection was in the order of 100:50:1.

Seed Collecting

Set against the background of the CBD and the IU, collecting should only be carried out with the permission of the national and local authorities. Foreign collectors should work collaboratively with local scientists and clear agreements on benefit sharing should be in place. One immediately tangible benefit is the sharing of collections and the information relating to them. Other international regulations need to be adhered to. These include the Convention on International Trade in Endangered Species (CITES) and national quarantine laws.

Seed collecting methodology and genetic resource exploration have been thoroughly covered by Guarino *et al.* (1995). In most instances, random and even sampling of wild plant or crop populations is recommended, including careful note taking of the sample method (in often less than perfect conditions). Objective data recording is essential as is accurate recording of location. This latter aspect is now facilitated by the use of Global Positioning System receivers that help fix latitude, longitude, and even altitude using satellites.

Harvesting seed that is close to maturity and keeping the seed alive in the field should be paramount. Also it is essential that harvested seed is returned to the seed bank facility as securely and rapidly as possible. Prestorage conditions influence seed viability at the start of storage. Because the longevity of a species stored under specific seed bank conditions is substantially fixed, the only other key longevity factor that can be varied is initial seed storage viability. Delay in drying the seed properly or unduly harsh cleaning methods can severely reduce initial viability; in turn, this can dramatically reduce both seed longevity and seed bank efficiency. Where space is not limiting within a cold store and the longer seed lots can be kept alive, the less the unit fuel cost per species.

It is worth noting that seed lots of the same species should not be mixed either within or between years. Such action

could diminish both the unique genetic makeup and reduce the longevity (through lower initial seed quality) of a seed lot.

Seed Cleaning

Seed lots harvested from some populations of wild species in particular contain large numbers of "empty" (or aborted) and insect-infested seeds. They may be outwardly similar to the "competent" seed and often are thus not removed during the cleaning process. Their presence can be detected by X-ray analysis or a simple cut-test applied to a subsample. Once detected, such incompetent seeds need to be allowed for when distributing seed to users and when carrying out germination tests. Although the insects may not be removed at this stage, nearly all adult and most larval forms of insects are killed by standard seed bank practice. However, insect eggs along with fungal and viral contaminants can survive seed banking. Thus, appropriate quarantine procedures need to be in place when the seed is removed from store.

Seed Bank Storage Standards

No two banks are the same. Traditionally, seed banks have been classified into the following categories:

- *Base* collections that are for the long-term storage of seed lots and from which seeds are not normally sent to users (though this is not always the case).
- *Active* collections from which seeds are made available to users. Often such stores are maintained under less optimal storage conditions compared to those holding base collections though this need not be the case. [FAO/IPGRI \(1994\)](#) recommends that storage lives of 10 to 20 years might be appropriate.

Base and active collections can occur at the same or different genetic resources centers or, as is the case in the SADC genetic resources network, the active facilities in different countries are linked to a regional base facility. In theory, the collections held within the active store need occasionally to be refreshed by the same samples held in the base store. Because active stores are likely to more frequently regenerate (discussed later) their samples, selection and genetic drift could cause a genetic divergence from the same samples held in the base store.

The [FAO/IPGRI standards \(1994\)](#) for base collection storage requires fresh seed to be dried within the range of 3 to 7% moisture content, packaged in a moistureproof way, and placed at subzero (and preferably -18°C) temperatures. Although many of the world's seed banks aspire to such conditions, as has been noted, relatively few are able to emulate them. Nonetheless, the robust nature of seed bank technology means that substantial longevities are achievable even with partial fulfillment of the standards that have been discussed and using a low technology approach.

The standards set out in 1994 are important as they set the benchmark for standard operating procedures by seed banks. Consolidation of these standards and increased use of a common format for data would facilitate exchange of information between facilities. Such unification of data standards could ultimately embrace all specimen banks including those

specializing in the storage of samples for environmental monitoring.

Seed Drying

Drying is perhaps the key to success in seed banking of orthodox-seeded species. Not only is storage prolonged in orthodox-seeded species but germination is prevented, the risks of insect and mite attack are reduced, and the seeds are protected from freezing damage. FAO (1996) found good drying facilities to be a limiting factor in a number of seed banks. Drying involves the manipulation of the water potential gradient between the inside and the outside of the seed. To all intents, the water potential is the difference between the activity of water molecules in any system compared with pure water. When the water potential of the air is lower (more negative) than that of the seed, there is a net movement of water out of the seed and drying occurs. As the water potential gradient reduces, drying slows down. When no gradient exists, the seed moisture content is said to be in equilibrium with the surrounding air conditions. Consequently, factors that influence the water potential of the air surrounding the seed are important to drying. Lowering the relative humidity or increasing the temperature of the air lowers its water potential. By keeping air moving over the seed, low humidity can be maintained by preventing moist air from accumulating around the surface of the seed. Seed size and seed depth affect rate of drying. Migration of moisture from the center of a large seed to the outside will take longer than from the center of a small seed. The same principles apply to large and small seed sacks. Shape, affecting surface to volume ratios, and seed structure will also have an effect on drying rate as can seed maturity.

It is worth noting that at any particular water potential, the seed moisture content will depend on its chemical composition. Seeds with a higher oil content will have a lower moisture content.

Most seed banks are located where the ambient relative humidity is not sufficiently low to allow the seeds to dry to the moisture content levels set out in the previous standards. High temperature gives rapid drying. However, although shade and oven drying can be used for drying, there are seed aging dangers of placing wet seeds at high temperatures and of leaving dried seeds too long under such regimes. Similarly, sun drying has risks associated with radiant heat gain. A degree of caution needs to be exercised if these methods are used. Consequently, seeds are usually placed in a drying environment where the relative humidity has been artificially lowered. Most often, this is achieved by sorption or occasionally by refrigeration drying systems. At their simplest, sorption systems can consist of a closed container into which the wet seeds are placed and the air dried by a quantity of silica gel or dried rice. Such methods require a degree of experimentation to achieve the desired results. Greater control over the extent of drying can be achieved by use of a suitable saturated salt solution (e.g., that of lithium chloride) that will maintain a set relative humidity (about 11% at room temperature) within a closed container. However, many of the larger seed banks have now adopted controlled drying rooms that allow for large samples to be dried in thin layers. Air from the chamber is dried using dryers containing lithium chloride or silica gel,

cooled, and then returned. In effect, this is a closed system though most facilities allow for some fresh air intake. Ducting the air to and from the dryer on opposite sides of the chamber encourages air movement. Conditions within the chamber are those necessary to achieve the desired moisture contents at equilibrium for long-term storage. Such conditions may be 10 to 15% relative humidity at 10 to 25 °C, and equilibrium is usually achieved in about one month.

Packaging

Maximizing orthodox seed longevity depends on drying and freezing. Cooling ambient air increases its relative humidity and hence its water potential. Placing the dried seeds directly inside a refrigerator will cause the seeds to absorb moisture. Therefore seed banks need to carefully package the dried samples. In 1996, IPGRI reviewed the types of container used in conventional long-term seed stores. Types of container used by banks include laminated aluminum foil bags, sealed steel cans, sealed glass tubes, screw-top glass bottles, and levertop fruit preserving jars. All containers have some limitations but, carefully managed, risks of moisture ingress can be minimized especially if some monitoring system is in place. The type of container chosen will partly depend on the frequency of access required. The main concern with all is that the seal through ingress of moisture through the fabric of the material over long periods is a risk where foil is punctured or cans have poor seams. Glass offers the advantage that the contents are visible but is of course at risk from breakage. A number of banks double-pack for added security and others add a desiccant. A number of facilities dry the air in the cold store and store the collections in paper or cloth bags. Consequently, these facilities must have adequate generator backup. This is less of a problem where seeds are held in moisture-proof containers and there is a loss of electrical power. In such circumstances there is little evidence to suggest that more than a few days storage life is lost per disruption.

Storage Temperature

Many long-term seed banks store seed under deep freeze conditions using either purpose-built prefabricated cold rooms or domestic deep freezers. To reduce staff time at sub-zero temperatures, a few seed bank cold rooms, such as one at the National Institute of Agrobiological Resources (NIAR), Japan, have mechanized banking/retrieval systems. The use of such systems have implications to energy consumption by the bank.

Use of permafrost has been considered for long-term duplicate storage of seed in places such as Svalbard. Although the dependence on electricity is cut, such stores are usually unable to match the lowering of temperatures possible in conventional base storage conditions. In 1997 the Japanese-based Biological and Environmental Specimen Time (BEST) Capsule 2001 Project discussed the possibilities of long-term storage of flagship samples under Antarctic ice at -58°C (which incidentally is not sufficiently low for animal tissue preservation) or even on the dark side of the moon at -230°C .

More usually, seed storage at ultra-low temperatures (cryopreservation) is achieved using liquid nitrogen. Seed samples are normally held in polypropylene (or similar) screw-cap containers placed in the vapor phase above liquid

nitrogen (about -160°C). Preferably samples of dry seed should be cooled and rewarmed at a relatively slow rate (about $10^{\circ}\text{C min}^{-1}$) to reduce problems of rapid thermal contraction and expansion that can cause physical injury to the seeds, such as cracking of the embryo tissue. The largest cryogenic seed bank is operated by the National Seed Storage Laboratory (United States) where there are more than 37,000 accessions stored over liquid nitrogen. More than 11,000 of these are also stored under conventional seed bank conditions at -18°C . The National Bureau for Plant Genetic Resources in New Delhi also conserves seeds under conventional and cryogenic storage conditions. Moreover, seeds of a significant number of North American and Australian wild species have been tested successfully for their tolerance of cryopreservation (Pence, 1991; Touchell and Dixon, 1993). It is worth bearing in mind when considering setting up a cryogenic facility for seed material that such low temperatures are not necessary to achieve practical periods of long-term storage (Pritchard, 1995), that the setup costs are relatively expensive, and the storage volume is less efficient than a conventional seed bank. However, these additional costs may be acceptable when creating the ultimate "base collection" for material that is in short supply, is inherently short-lived, or is of particular commercial value (unique genotypes).

Monitoring Seed Lot Viability

Perhaps one of the most important parameters of seed bank effectiveness is the result of germination monitoring. Germination is the preferred test for seed lot viability. Providing such information to those using the seed is helpful. Additionally, other viability tests such as vital staining using tetrazolium solution have a greater element of subjectivity about them. This staining test is, however, sometimes used to help distinguish between dead and dormant seeds among those that did not germinate under a given test regime. Two problems relate to the germination monitoring of seed bank accessions. First, because seeds are tested soon after arrival at the bank and then at regular intervals (often every 5 to 10 years) during their storage life, the tests need to be repeatable and operator independent. Second, in order to recover as many genotypes as possible represented within a seed lot, it is necessary to break seed dormancy. This can be a particular problem in seed of wild species and where the seed is freshly harvested. Key techniques include scarification of hard seed coats to facilitate water or oxygen permeation, imbibed chilling at 5 to 10°C , and later incubation at diurnal alternating temperatures with fluorescent light (i.e., rich in red light) provided only in the higher temperature phase. Tests have to be seed lot specific as most seed dormancy is not strongly genetically inherited and the form it takes depends on the conditions under which the seed matured. Once determined, the same treatments can be used during the monitoring of that seed lot through time.

Seed banks use a variety of media for germinating the seeds, such as filter paper and sterilized sand. However, 1% (w/v) plain water agar is increasingly popular especially as it reduces the risk of imbibition damage to dry seeds.

Obviously through time these monitoring tests can consume a significant proportion of each seed lot. Ideally, when the seed viability has fallen to a level where regeneration needs

to take place, sufficient seeds should remain in the collection to make several attempts at growing out the collection. Because base collections may have a projected storage life of as much as 200 years, collection size needs to be large. The international standards (discussed earlier) recommend at least 1000 seeds per seed lot.

Where seed banks handle seed with unknown storage behavior, the initial germination could be delayed until after drying and banking. Survival will indicate orthodox characteristics. Few banks will have sufficient staff time to do more than brief tests prior to this on suspected recalcitrant or intermediate seeded species.

Duplication

One of the main advantages of seed banks is that they centralize collections of genetic material making them more easily accessed and studied. Indeed, some seed banks might be seen as some of the world's greatest plant diversity hot spots with more individuals and, in some banks, more species per square meter than anywhere else on the planet. This centralization poses a risk to all but the most carefully located and constructed facilities. Potential catastrophic loss, which of course threatens plants conserved both *ex situ* and *in situ*, mean that duplication of collections and their associated data is an important element of seed bank safety. The FAO report (1996) indicates that the level of security duplication of plant genetic resources for food and agriculture still needs to be improved and is at best uncertain.

Characterization and Evaluation

Characterization can vary from accurate naming of the species or subspecies represented by the collection through to more detailed recording of characters governed by genes that are little modified by environmental factors (major genes). Such information, published in the form of descriptor lists, is of great value to plant breeders wishing to narrow their choice of material from, often, vast collections. Similarly, the concept of core collections has been established to facilitate use by breeders. A core collection genetically represents a limited set of accessions of a crop gene pool with the minimum of repetition.

Increasingly, characterization is taking the form of more detailed molecular techniques such as screening by Amplified Fragment Length Polymorphism. By contrast to characterization, evaluation records data on traits such as yield that are strongly influenced by the environment in which the plants are grown. Such data are thus site and year specific and are perhaps of less use to breeders.

Distribution to Users

A very important element of seed bank work is to make the seed available wherever possible. In evidence of the scale of such dispatch, ten Kate and Laird (1999) quote an annual distribution of nearly 120,000 samples by the U.S. National Plant Germplasm System of which 65% are sent abroad, many requested by reference to the Germplasm Resources Information Network (GRIN) available on the Internet. Furthermore, the usage rate of crop banks by plant breeders is probably less than the rate of request from banks holding

broader plant diversity collections where uses include a wide array of pure and applied research in addition to field trials. During 1994–1996, there was a 50% request rate for seeds offered through an extensive list offered by the Kew Seed Bank.

Several elements need to be considered concerning the distribution of seed to users. The recipient should be provided with accurate information about the collection and how to germinate the seeds. It should also be remembered that certain species require a symbiont for effective growth (e.g., legumes and *Rhizobium*), and that the user may need to draw on germplasm for both plant and symbiont. The seed sample must be dispatched having fulfilled all necessary plant health and, where appropriate, CITES requirements. Finally, to meet the needs of the CBD and to clarify the conditions under which the material can be used, all germplasm samples are increasingly dispatched under material supply agreements.

Regeneration

Seed bank accessions are grown out for the purposes of regeneration of seed stock (either when seed numbers are low or when viability has reduced), for characterization and for evaluation. Many banks have a regeneration standard below which the germination of a seed lot should not fall. This is usually set at 85%. This high value limits the risk of accumulated genetic damage that is associated with seed aging. Even though falling levels of seed germination are correlated with falling levels of field establishment, many banks have adopted lower standards. This may in part be due to the backlog of regeneration work that in some national facilities highlighted by FAO (1996) is nearly 100% of the collection. By collecting high-quality seed lots in good quantity, other banks have reduced the necessity for regeneration that can be time and labor consuming and that can have adverse effects on the genetics of the collection. Samples regenerated under conditions different from where they originated can experience selection. If too small a sample is regenerated, genetic drift may occur in which rarer alleles are lost through chance. Under some circumstances, recollection, if possible, may be the more desirable option.

Seed Bank Design

Having considered the aspects of seed bank management, a brief consideration of seed bank design is appropriate (also see Cromarty *et al.*, 1985). The location of the bank is important from political, practical, and security aspects. Potential risks have to be considered be they earthquake, flooding, or radiation fallout. Some facilities are placed underground such as the seed bank at Krasnodar in Russia and the Millennium Seed Bank in the United Kingdom. Others such as the NSSL are located on the first floor to limit possible impact from structures above resultant from seismic activity. The size of most banks should be dictated by peak annual intake (seed drying and cleaning facilities), projected capacity before a rebuild is practical (seed storage), and annual collection maintenance (germination, field, and greenhouse facilities). Cold storage facilities vary from a few domestic deep-freezers up to large rooms such as one of 140 m² (with capacity for 150,000 samples) at NIAR in Japan.

Other Types of Gene Bank

This section provides summaries of the current status of nonseed gene banks, starting with dry propagules (pollen and spores), which can be stored under conditions similar to those used for seeds, and covering normally hydrated tissues that can also be preserved under a different set of controlled conditions. Finally, field gene banks are covered and the role of botanical and zoological gardens is briefly mentioned.

Pollen

There are many practical reasons for storing pollen: to support work on allergenic responses, plant hybridization, and fertility; haploid plant production; and genetic transformation systems with isolated pollen (or gametes). Optimal storage conditions for pollen are similar to those for seeds (i.e., at low moisture content and subzero temperatures). In addition, there is some evidence (e.g., in maize and *Impatiens*) that longevity in dry storage is enhanced in anoxic atmospheres. Moreover, pollen has also been stored in a vacuum-dried state. The ease of storage though relates in part to the cellular and physiological nature of the pollen. Bicellular pollen, as found in Liliaceae, Orchidaceae, Solanaceae, and Rosaceae, generally tolerates desiccation to about 10% moisture content and is relatively long-lived. By comparison, tricellular pollen, as found in Graminae and Compositae, is relatively short-lived and is much more sensitive to desiccation. Most work on the long-term storage of pollen has focused on fruit tree or forestry species, for which 10 years storage at conventional gene bank temperatures (–20 °C) is easily attainable. Pollen of at least 30 species are known to survive liquid nitrogen temperatures. Although pollen banking is evidently possible for many species, there does not appear to be any large-scale gene bank operation using such material.

Spores

Spores of many species of both pteridophytes and bryophytes are stable for months or years when dried, and this time can be extended with storage at cold or freezing temperatures. The longevity of short-lived (chlorophyllous) spores of some species can be extended significantly by drying and freezing in liquid nitrogen (Pence, 2000). Although there are data on fungal spore storage (e.g., work by Hong *et al.* in 1998), the majority of fungal germplasm appears to be conserved in culture or through cryopreservation of hyphae (see later).

Somatic and Zygotic Embryos of Plants with Nonbankable Seeds

Nonbankable seeds can nonetheless be stored using alternative approaches. Usually, these revolve around the use of rapid, partial desiccation of embryos or embryonic axes to about 20% moisture content and subsequent transferal to liquid nitrogen temperature or the use of other subzero storage temperatures. Recovery levels may be improved by pretreatment of embryos with cryoprotectants, encapsulation of the material in alginate beads, or careful manipulation of the

in vitro recovery environment. The embryos of more than 50 species have been successfully cryopreserved. Other parts of the plant can also be used to establish *ex situ* gene banks for species with nonbankable seeds, as described in the following section.

Vegetative Parts of Plants

Vegetative tissues of both pteridophytes and bryophytes can be banked for germplasm preservation (Pence, 2000). Gametophytes of many bryophyte species are naturally adapted to desiccation stress and can be cryopreserved after sufficient drying. Gametophytes of pteridophytes and some desiccation-intolerant bryophytes can also be frozen when provided with some cryoprotection, such as encapsulation in alginate beads followed by dehydration or the use of abscisic acid and the amino acid, proline, as a pre-treatment. Shoot tip freezing of sporophytes of pteridophytes has also been demonstrated. It is estimated that fewer than 200 taxa of bryophytes and pteridophytes combined are currently banked worldwide using vegetative tissues, primarily at the Cincinnati Zoo and Botanical Garden and the University of Kansas in the United States, but there is significant potential for increasing this number.

The National Seed Storage Laboratory of the U.S. Department of Agriculture (USDA) also cryopreserves about 1700 apple lines using dormant scion sections, which are retrieved by grafting (i.e., no culture of meristems). The lines are mainly from *Malus x domestica*, plus 10 to 15 other apple species. Some pear and cherry species (Towill and Forsline, 1999) are also banked in this way.

Apical shoot tips and other meristems/buds are the most popular vegetative materials for cryopreservation. Lines from about 50 species are now routinely cryopreserved. Initial studies used shoot tips from cold hardy, temperate zone species (apple, pear), but cryopreservation methods have been extended to tropical zone species (banana, pineapple). Successful cryopreservation depends on defining the physiological adaptation of the stock plant, the explant size and type, and its water content, the steps in the preservation process (cryoprotectant concentrations and rates of addition/removal; cooling/warming rates), and the recovery system. Two-step cooling procedures have been useful for some species, but vitrification procedures (solution-based systems and encapsulation/dehydration systems) are more favored because of the technical simplicity (Sakai, 1993). All methods are designed to reduce ice crystal growth in the specimen. Other vegetative material that has been cryopreserved using similar methodological approaches include cell suspensions and callus (more than 40 species), protoplasts (more than 10 species), and root cultures (5 species).

It should be noted that cryopreservation of vegetative germplasm overcomes the problem of genetic instability during storage as all cellular divisions and metabolic processes are stopped. In contrast, two other methods of *in vitro* preservation, normal and slow growth techniques, run the risk of genetic changes (somaclonal variation) in the conserved germplasm that may result in the loss of distinct genotypes.

Species are stored under normal growth conditions (e.g., *Coffea* at 27 °C) for short-term purposes only. The explant

(usually meristem or nodal cutting) is frequently transferred (subcultured) to fresh nutrient medium with the risk of microbial contamination, or loss through human error. To retard growth and hence extend the subculture interval, temperature and light intensity are reduced. For example, 0 to 5 °C and 1000 Lux are generally used for cold tolerant species, and 15 to 22 °C and reduced light intensity for tropical species. Alternatively, growth can be slowed down by the addition to the medium of chemicals to induce mild osmotic stress (e.g., mannitol) or hormonal retardants (paclobutrazol, abscisic acid). Also, maintenance of tissue under reduced oxygen (e.g., under mineral oil or liquid medium) slows growth. Under the appropriate conditions subculture intervals can be extended to one year or longer. The slow growth technique is now routinely used for the medium-term conservation of a number of species such as banana, potato, yam, cassava, and strawberry.

Although *in vitro* culture without cryopreservation poses considerable threat of genetic drift, the propagation of plant material in an aseptic environment ensures the production of disease-free stock material, which is readily accessible internationally because it satisfies most country quarantine requirements. Undoubtedly, *in vitro* culture is a valuable complementary approach to field conservation and is particularly useful when applied to species that are predominately propagated vegetatively (banana, potato, and pear), produce non-bankable or highly heterozygous seeds, and have a particular gene combination (i.e., elite genotypes; see Ashmore, 1997). The impact of these positive features of the technique is such that FAO estimates that 37,600 accessions of plant material (vegetative and embryos) are conserved *in vitro* (including cryopreservation) worldwide.

Animal Germplasm Samples

A majority of *ex situ* animal germplasm is maintained in zoological gardens and institutes around the world. The NIAR in Japan holds 621 accessions of animal germplasm, including silk worms in the living state. More than 100 of these accessions, mostly sperm, are cryopreserved (for a general methodology, see the discussion presented later). Similarly, the main gene bank methodology for ova is cryopreservation. At present, however, procedures for sperm and ova preservation are not well developed for wild species, even though a number of reported successes with artificial insemination and frozen semen can be found in the literature, especially for ungulates such as deer and antelopes. The concept of gamete rescue from tissues has considerable value for spermatozoa, where epididymal spermatozoa are readily obtainable post mortem and can be frozen using glycerol as a reasonably standard cryoprotectant. Oocyte cryopreservation has only been achieved in the hamster, rat, rabbit, and cow and is therefore not a practical proposition at present. Interest in freezing ovarian tissue, and then culturing follicles and oocytes by various methods after thawing, has recently been resurrected and progress has included the birth of a lamb originating from ovarian tissue autotransplanted into the donor-recipient after freezing and thawing. In another recent study, isolated rat spermatogenic cells were transferred to a mouse testis, where they displayed the ability to develop into

Table 1 Collections Maintaining Microorganisms

Collection	Location	Number of strains	Type of material
Agricultural Research Service Culture Collection, USDA	Peoria, IL (US)	78,010	Algae, bacteria, fungi, yeasts, actinomycetes
American Type Culture Collection (ATCC)	Rockville, MA (US)	53,615	Algae, bacteria, fungi, yeasts, protozoa, cell lines, hybridomas, viruses, vectors, plasmids, phages
CABI Bioscience UK Centre (formerly IMI)	Egham, UK	21,000	Fungi, bacteria, yeasts
Centraalbureau voor Schimmelcultures (CBS)	Baarn, The Netherlands	41,300	Fungi, yeasts, lichens, plasmids
Culture Collection, University of Goteborg (CCUG)	Goteborg, Sweden	28,100	Bacteria, fungi, yeasts

spermatozoa. The testicular cells were frozen-thawed prior to transplantation and development, and thus there may be some merit in exploring the cryopreservation of testicular cell suspensions as an alternative or adjunct to the preservation of spermatozoa. Cell suspension from genetically important animals could be used to populate the testes of common species, thus permitting the eventual harvesting of spermatozoa. It should be stressed that this technique is still only in its infancy.

Unlike animal species in which reproductive cells and tissues are stored to conserve the gene pool, in humans they are stored for the use of the couple/woman electing to have them cryopreserved. Some embryos are subsequently donated for the treatment of others. Storage is limited by law in some countries.

The storage of embryos is common practice in *in vitro* fertilization (IVF) clinics worldwide, with about 70 offering the service in the United Kingdom alone. Oocyte cryopreservation is poorly developed and few clinics store them other than for research. An increasing number are offering tissue storage.

Despite sporadic reports of cryopreservation using nonequilibrium rate cooling, the vast majority of clinics prefer conventional slow cooling rate procedures with the samples loaded into "straws" (embryos and oocytes) or plastic vials (ovary). The first step involves the addition of the cryoprotectant (about 1.5 M; 1–2 propanediol $\pm$ sucrose (pronucleate and early cleavage stage embryos), dimethyl sulfoxide (4–8 cell embryos, and ovary) or glycerol (blastocyst stage embryos)). Ice formation is then induced at -5 to -7 °C and the samples are cooled further at rates of about 0.3 to 0.5 °C per minute to various subzero temperatures before storage in liquid nitrogen. After warming at appropriate rates (of about 20 to more than 300 °C per minute), the samples are returned to isotonic conditions stepwise, with or without the addition of sucrose to the diluent.

Microorganisms

The most widely applicable preservation method for the preservation of microorganisms that retains viability and stability is cryopreservation. However, for convenience and ease of transport freeze-drying is preferred for most bacteria, viruses, and sporulating fungi (see Hunter-Cevera and Belt, 1996).

There are currently 497 collections from 60 countries maintaining microorganisms registered with the World Data Centre for Microorganisms in Japan (see Sugawara and

Miyazaki, 1999). Their on-line database lists species held and the expertise and services provided by the collections along with contact addresses and links to collection websites. There are about 11,500 species held. Over 25% of the strains are held by 5 of the 497 collections (see Table 1).

DNA Banks

DNA banks have been established in several places worldwide (Adams, 1997), the largest (more than 140,000 clones) being for plant and animal material at the NIAR in Japan. This collection is mainly constituted of rice clones (about 36,000 comprising Random Fragment Length Polymorphisms, cDNA, YAC) and pig clones (about 106,000 comprising cosmids, BAC, cDNA). The most diverse DNA bank for plants is at the Royal Botanic Gardens (RBG) Kew, which currently holds more than 10,000 DNA samples from a wide range of species. Standards of quality of preservation differ between banks and some, such as those at the Missouri Botanical Gardens (St. Louis, Missouri, in the United States) and several zoos, store only frozen tissue. Others extract DNA and purify it to varying degrees. Purposes for these banks differ as well, with some established to hold samples of a particular country or region with the intent of using these in conservation genetic studies, whereas others focus more on taxonomic and systematic studies, such as that at RBG Kew. Most banks are prepared to consider sharing aliquots of DNA or small samples of tissue with researchers at other institutions.

Field Gene Banks

Field gene banks are *ex situ* collections of mainly agricultural or forest species. They should be contrasted with what might be termed "farm gene banks" where crop germplasm is, in effect, conserved *in situ* by the farmer. Field gene banks normally comprise considerably more individuals per accession than is the case in botanic gardens. Their particular use is for the conservation and utilization of species with the following traits:

- Have nonbankable seeds
- Have long life cycles where growing up material for regular study from a seed collection is impractical
- Are normally vegetatively propagated

Essentially, they are not a new idea as the Kayapo people of Brazil maintain germplasm collections of tuberous plants in hillside gardens protected from flood (see Plucknett *et al.*, 1987). Most countries have at least one field gene bank and FAO (1996) estimate some 527,000 accessions are conserved in this way worldwide. Examples of field gene banks include the National Fruit Collection in the United Kingdom, one for cassava at CIAT, Colombia, one for sugarcane at the Centro Nacional de Pesquisa de Recursos Genéticos e Biotecnologia (CENARGEN), Brazil, and the potato collection at the Centro Internacional de la Papa (CIP) in Peru. Such facilities are considered by FAO to be particularly important in small island developing states. It should also be noted that the Nordic Gene Bank, which operates on a regional basis, unlike many seed banks, includes within its remit the *in situ* conservation of wild crop relatives.

While they offer the opportunity for characterization and evaluation, such collections are labor intensive and are susceptible to catastrophic events. For example, a field collection of yams was lost in St. Lucia during 1994 as the result of cyclone damage. This is one of the reasons that a number of field gene bank collections are now backed up *in vitro*.

Botanical and Zoological Gardens

Botanical and zoological gardens may be seen as types of gene bank with relatively few individuals per accession. While zoos have embraced careful breeding programs that help maximize the genetic value of the limited collections across the world, this is much less true of collections in botanical gardens. Here species may be represented within the 'botanical gardens flora' by a single genotype such is the clonal exchange of material.

Acknowledgements

The authors would particularly wish to acknowledge the following for their assistance in providing information: Mr. M. Ambrose (John Innes Centre, United Kingdom); Dr. D. Astley (HRI, United Kingdom); Dr. M. Fay, Mr. R. Smith and Mr. M. Way (RBG Kew, United Kingdom); Dr. W. Holt (Institute of Zoology, London, United Kingdom); Dr. S. Miyazaki and Mr. A. Yamamoto (NIAR, Japan); Dr. B. Panis (Leuven, Belgium); Dr. V. C. Pence (CREW, Cincinnati, United States); Dr. D. Smith (CABI Bioscience, United Kingdom); Dr. S-H Tan (CBS, Netherlands); Dr. L. Glossary

Allele A unique nucleotide sequence of a gene, which may or may not affect phenotypic expression.

Chromatin A complex of DNA and associated proteins that when assembled make up chromosomes of eukaryotes.

Chromosome A thread-like structure which can be visualized when condensed during cell division; consists of DNA and proteins.

DNA Deoxyribonucleic acid, the molecule of inheritance which stores genetic information passed from one cell to another and from one generation to succeeding generations, composed of four nucleotides: adenine (A), cytosine (C), guanine (G), and thymine (T).

Eukaryotes Organisms with genetic material organized into chromosomes contained within a membrane-bound nucleus in the cell—eukaryotic cells undergo mitosis and meiosis during cell division, ensuring the equal division of chromosomes among daughter cells.

Exons Parts of a gene sequence transcribed and translated into a protein; usually interrupted by introns which are spliced out of messenger RNA before translation.

Genetic code The language that specifies how DNA will be translated into amino acid sequences by means of three nucleotide “words” (codons) that specify the 20 amino acids and regulators of transcription (start and stop codons).

Heterochromatin Regions of chromosomes that in general do not include coding DNA, always remain condensed during a cell’s life cycle.

Introns Generally noncoding segments of genes, situated between exons and removed before translation of messenger RNA to proteins.

Locus A precise location in a genome, whether a gene is found there or not; in former times “locus” was used

interchangeably with “gene,” but the definition has become more specific in the era of molecular genetics.

Nucleotide Subunit of DNA and RNA, composed of a ringed five-carbon sugar, a ringed nitrogen-rich base, and phosphates; nucleotides are often referred to as base pairs because individual types form complementary hydrogen bonds (G-C and A-T in DNA, G-C, and A-U in RNA) to make double-stranded DNA and RNA molecules.

Organelle Membrane-bound structures within eukaryotic cells that carry out specific functions and often contain their own DNA; typical organelles are mitochondria and chloroplasts.

Posttranscriptional modification Cutting and splicing of messenger RNA, in some cases to produce alternative transcripts and proteins with different structural or regulatory properties (e.g., sex determination in *Drosophila*).

Prokaryotes Single-celled organisms defined by having their DNA arranged as a circular molecule not contained within a nucleus, and which reproduce by simple fission.

Repetitive DNA Regions of DNA that include the same DNA sequence repeated several hundred or thousand times; regions with repeated segments that involve only 2–5 base pairs of DNA are called microsatellites.

RNA Ribonucleic acid, composed of nucleotides like DNA, but in RNA the base uracil (U) replaces the base thymine (T), RNA molecules form important structural and regulatory parts of cells.

Transposable elements Also called mobile elements, jumping genes, or insertion sequences (in prokaryotes); fragments of DNA that contain genes that enable the DNA fragment to excise itself and then relocate into a new location in the genome.

Introduction

Understanding the mechanisms of heredity is a key to the study of biodiversity for at least three reasons. First, genetic variation provides the material for evolution—descent with modification—including adaptation within populations, diversification of lineages, and the formation of new species. Second, standing genetic variation within populations may reflect the recent history of populations and indicate prospects for change in the future. Third, variation in molecular genetic markers can be used to track the relationships among living groups of organisms and the taxonomic status of individual populations. Heritability of both adaptive and neutral genetic variation depends upon genes, defined as sequences of DNA

that specify cell structure, including proteins and several types of RNA. Genes also code for enzymes and proteins that bind to DNA or RNA to control gene expression and cellular physiology. In former times, the term “locus” was used interchangeably with “gene,” but today locus simply means a particular location in a genome, whether the DNA codes for a gene product or not. Locus may still be used to describe neutral molecular markers, where allelic variation at the DNA level is used to study population genetics, relatedness within populations, parentage, and genome mapping.

Genes and genomes are both complex and continually modified. Organisms share a common biochemical mechanism of heredity, but with characteristic differences that allow us to make hypotheses about the history of life. Examples

include the bacterial origins of mitochondria and chloroplasts in eukaryotic plant and animal cells. Variation in genomes is pervasive in nature, and continually arises by the inevitable and inexorable process of mutation, both on the level of individual nucleotides within DNA molecules and the level of chromosomal gene rearrangements. One of the most significant (and initially unappreciated) discoveries in genetics is that genomes are not static within organisms; transposable elements, for instance, can excise themselves from one locus and reinsert in another place in the genome. The original discovery of transposable elements was in maize by Barbara McClintock, who in the 1930s correlated regular breaks in chromosomes with the loss of purple pigment in corn kernels. Regaining the pigment was associated with similar breaks at other places in the genome. We now know these as “jumping genes,” which carry with them genes that control their ability to excise, duplicate, and reinsert into multiple places within genomes, sometimes carrying other genes with them, and sometimes disrupting genes at their insertion sites. Dozens of transposable elements are now known, and more continue to be discovered in an ever-widening sample of organisms (Li, 1997). As a consequence, it is no longer possible to view genomes as static entities, with genes aligned in precise locations that forever remain stable.

In this article, we describe genes in the context of entire genomes. In prokaryotes (bacteria and blue-green algae), genomes are organized as naked circular DNA molecules within the cytoplasm. In eukaryotes, most genetic material is in chromosomes—long, linear arrays of DNA bound with proteins—found within the membrane-enveloped nucleus. Genes in eukaryotes can also be found in prokaryote-like genomes inside cellular organelles like mitochondria and chloroplasts (the photosynthetic organelles of plants). All genomes contain regions of noncoding single-copy DNA and

repetitive DNA, which are used extensively in population genetic and phylogenetic studies as molecular markers. [Avise \(2004\)](#) provides an in-depth overview of the use of molecular markers in the study of evolution.

Structure of DNA and RNA

What follows may serve as a primer for those who are not conversant with molecular genetics. A full description of genes is not possible in the space of a few pages; those seeking more detail should consult other sources (e.g., Hartl and Jones, 2005; Lewin, 2004). Molecular genetics is a mushrooming field, but the salient features of genes are universal, and genes and the genetic code can be understood on an intuitive level without extensive knowledge of biochemistry. In general, genes are carriers of information working in a nested series from individual nucleotides, to short regulatory DNA or RNA sequences, to relatively large RNA molecules and enzymes composed of hundreds of nucleotides or amino acids, to enormous cell structure proteins comprising thousands of amino acids folded into complex three-dimensional shapes.

First and foremost, in this hierarchy of information are nucleic acids, DNA and RNA, which are the molecules of heredity for most life forms (one notable exception being prions, which are infectious proteins and cause the famed “mad-cow disease” and a number of neurological disorders in humans, [Prusiner and Scott, 1997](#)). Both DNA and RNA are made up of four nucleotide subunits linked together to form long chains ([Figure 1](#)). Nucleotides themselves are made up of three parts: ringed sugars, phosphates, and ringed nitrogen-and-carbon bases. Nucleotides are joined to each other to

Figure 1 DNA (and RNA) are composed of four nucleotide subunits, A, C, G, and T (U replaces T in RNA), each covalently bonded to a sugar, with sugars linked to each other by a phosphate bond (circled P) between the 3' and 5' carbon atoms of the adjacent sugars. Complementary strands of DNA are held together by hydrogen bonds (shown as broken lines). Of the two strands, the lower is in the 5'–3' direction, showing how nucleic acid sequences are usually written (GTCA).

form chains by bonds between phosphates and sugars. Nucleotides are complementary to each other in terms of the numbers of hydrogen bonds they form between bases: A (adenine) and T (thymine) form two hydrogen bonds, G (guanine) and C (cytosine) form three bonds. Two complementary chains intertwine to form double-stranded DNA or RNA by hydrogen bonding. Double-stranded DNA molecules form the classic “double-helix,” where two chains of nucleotides joined by hydrogen bonds spontaneously form twists of $\sim 36^\circ$ so that ~ 10 base pairs make a complete 360° turn. DNA can take on a number of other forms, such as supercoiled, depending upon temperature, pH, and the nucleotide sequence.

RNA can also form a double helix, but one with a broader diameter. An additional feature of RNA is that single-stranded molecules include complementary sequences that allow the single-stranded RNAs to fold back on themselves, forming double-stranded helical stems and other three-dimensional grooves, knobs, and loops (Gutell, 1996). Three-dimensional structure is a vital characteristic of the long ribosomal RNA (rRNA) subunits of ribosomes, and the shorter transfer RNA (tRNA) molecules that are part of the translation machinery for processing messenger RNA (mRNA) into protein.

Genes

The number of genes within organisms varies tremendously between viruses, bacteria, and multicellular eukaryotic organisms. For instance, it is estimated that humans have $\sim 25,000$ – $40,000$ genes, the fruit fly *Drosophila melanogaster* 13,767, the nematode worm *Caenorhabditis elegans* $\sim 19,000$, the mustard *Arabidopsis thaliana* 25,500, the yeast *Saccharomyces cerevisiae* 6275, the bacterium *Escherichia coli* 4286, and the human immunodeficiency virus (HIV) RNA retrovirus 9. For the organisms whose entire genomes have been characterized and whose complete nucleotide sequences are known (*Drosophila*, yeast, worm, *E. coli*, and HIV), the number of protein-coding genes is known with accuracy. For others, the numbers represent estimates based on incomplete sequencing and lack of similarity to previously identified genes from other species. For instance, early estimates of the number of genes in humans have been as high as 140,000 genes. The number of identified genes is bound to increase within each kind of organism, with the possible exception of viruses. In part, this is because novel mechanisms of inheritance and gene regulation by RNAs continue to be discovered (Pearson, 2006).

The flow of information within a cell generally follows a pathway, with genes coded in DNA transcribed into three types of RNA, followed by translation of the nucleotide sequence in mRNA into chains of amino acids (proteins and enzymes). This process of information transfer, which has been called the “central dogma of molecular biology,” is depicted in Figure 2. Two types of genes result from the transfer of information from DNA to proteins. The first type may encode enzymes such as DNA polymerases, soluble enzymes, and transcription factors that control the metabolic and biochemical processes within a cell. The second type encodes the physical structures of the cell, including cytoskeleton proteins like tubulin and actin that affect cell shape, and subunits of

rRNA that comprise the machinery of protein translation. The majority is expressed as proteins and enzymes, and the majority of proteins and enzymes is involved in cellular regulation rather than cell structure.

Protein and enzyme coding is specified by the genetic code (Table 1), which contains the language of protein synthesis. The genetic code has a series of three-base-pair codons that specify 20 amino acids as well as codons that signal translation to “start” and “stop.” The genetic code is almost universal, although there are a number of differences between nuclear and mitochondrial DNA (mtDNA) in eukaryotes and there are unique codons in a few bacteria and Protista (Li, 1997). The code functions by specifying three-base-pair codons of mRNA that match three-base-pair anticodons found on a loop of the tRNA. Each tRNA is specific to a particular amino acid. The complex dynamic molecular structure involved in translation of the genetic code contains mRNA, ribosomes (rRNA plus proteins), and tRNAs.

Because DNA contains specific information, transcription and translation must proceed in only one direction for the information to be communicated accurately. This is analogous to the conventions followed in most written Indo-European languages, where words form sentences that are read on a page from left to right. The direction along any strand of DNA or RNA can be identified by which carbon atoms of the ringed-sugar-and-phosphate backbone are bonded together. Carbons in the ribose sugar are numbered 1–5, and bonds occur between a phosphate attached to the 5' carbon of one sugar with a hydroxyl group attached to the 3' carbon of the next. Consequently, directionality can be specified along each nucleic

Figure 2 The flow of information from DNA to proteins. DNA is transcribed into three types of RNA, which then combine to read the genetic code and translate the information into proteins (or enzymes).

	GUG	GCG	GAG GLU	GGG	G

^aThe three stop codons (UAA, UAG, and UGA) and the start codon for methionine (AUG) are shown in bold. Most amino acids are specified by more than a single codon, with several (arginine, leucine, and serine) specified by six codons. There is a weakly positive general relationship between the frequency of incorporation of an amino acid into proteins and the number of codons specifying the amino acid. In most cases, a change in the third position in a codon does not result in a change in the amino acid because most tRNA anticodons will still bind to mRNA codons if the first two positions on the mRNA match the tRNA. This is the so-called wobble effect and redundancy in the genetic code.

acid molecule, and the genetic code must follow this direction for the language of transcription and translation to be faithfully transmitted. For instance, RNA polymerases transcribe by adding new nucleotides to the 3' end of a growing RNA molecule, and so create the RNA in the 5'–3' direction. However, transcription is from a complementary DNA chain that is read in the 3'–5' direction. In general, reading frames of DNA are written by placing the 5' end on the left, and protein sequences are written in the same left-to-right direction specified by the nucleotide sequence (e.g., Table 2).

Prokaryotic Genomes

The genomes of most prokaryotes (bacteria and blue-green algae) are composed of one double-stranded circular DNA molecule attached to a central core of proteins in a series of supercoiled loops emanating from the center like the cotton fibers of a dust mop. Although the nucleoid “chromosome” is not enclosed within a nuclear membrane, it tends to be found in a particular part of the cytoplasm. An additional feature of prokaryotes is their ability to acquire smaller circular DNA molecules, called plasmids. Plasmids contain numerous genes, including genes found in the chromosome. Transfer of plasmids into and out of bacterial cells makes them useful in DNA-based biotechnology and is responsible for the rapid transfer of antibiotic resistance genes between bacterial strains.

Genes in prokaryotes are collinear and uninterrupted, in that one to several genes are expressed in the order in which they follow a promoter. Transcription of mRNA leads directly to translation with little modification (Figure 3). This arrangement of several genes being expressed as a group is sometimes referred to as polycistronic, and is restricted to prokaryotic and organelle genomes.

The control of gene expression in prokaryotes is through either positive or negative regulation. Under negative regulation, like that found in the tryptophan operon of *E. coli*, a repressor protein combines with a tryptophan molecule and then binds to the repressor region of the gene, turning off transcription when tryptophan becomes common within the cell. Under positive control, a transcription factor must bind with the regulatory site to initiate transcription. This is part of the *lac* operon of *E. coli*, one of the earliest metabolic pathways described at the molecular level by Jacques Monod and colleagues at the University of Paris. The *lac* operon is mainly under the negative control of a repressor that is removed when lactose is present in the cell. However, transcription also depends upon a second protein that must bind for transcription of RNA. This double control allows the bacterial cell to turn off the *lac* operon when glucose, a preferred food source to lactose, is present in the cell.

Eukaryotic Genomes—Chromosomes

The genomes of eukaryotic organisms are characterized by DNA arranged in long linear molecules and associated proteins in a complex structure known as chromatin, which is contained within a membrane-bound nucleus. Chromatin is in a diffused state during interphase of the cell cycle when transcription and translation occur. When the chromatin coils and condenses during cell division, it forms itself into microscopically visible threads in the nucleus. These threads are called chromosomes. The number of chromosomes found in different eukaryotic groups varies considerably, but each group displays a characteristic range of chromosome numbers. For example, humans and great apes have haploid chromosome numbers of $N=23$ and $N=25$, respectively, while

Table 2 Types of mutations: (A) chromosomal mutations (very small fragments are illustrated; chromosomal mutations usually affect large chromosomal fragments, and (B) gene mutations

A. Chromosomal mutations		
	DNA sequence (of a chromosome)	Type of mutation
Original sequence	AGTTCGTAGGGTACCTGATCGACG	
Mutant sequences	AGTTCGTACCTGATCGACG	Deletion of AGGGT
	AGTTCGTAGGGTACCTGAT CATGAG CGACG	Insertion of CATGAG
	AGTTCGTAGG TCCATG GATCGACG	Inversion of GTACCT
	GACGG TAGGGTACCTGAT CAGTTC	Translocation of AGTTC and GACG
	AGTTCGTAGGGT ACCTGACCTG ATCGACG	Duplication of CCTGA
B. Gene mutations		
	Three-base-pair codons (top line), and the proteins specified (lower line)	Type of mutation
Original gene	AUG UGG UGU GAG UAC AUU CGA GAG AAG UAG met-trp-cys-glu-tyr-ile- arg-glu-lys- stop	
Mutant genes	Mutations at the third codon	
	AUG UGG UGC GAG UAC AUU CGA GAG AAG UAG met-trp-cys-glu-tyr-ile- arg-glu-lys- stop	Synonymous (no amino acid change)
	AUG UGG UCU GAG UAC AUU CGA GAG AAG UAG met-trp-ser- glu-tyr-ile- arg-glu-lys- stop	Missense (amino acid change)
	AUG UGG UGA GAG UAA AUU CGA GAG AAG UAG met-trp- stop	Nonsense (mutation to a stop codon)
	AUG UGG UUG AGA GUA AAU UCG AGA GAA GUA G met-trp-leu- arg-val-asn-ser-arg-glu-val-	Nonsense (insertion and shift of reading frame)
	AUG UGG GAG AGU AAA UUC GAG AGA AGU AG met-trp-glu-ser-lys-phe-glu- arg-ser-	Nonsense (deletion and shift of reading frame)

**Figure 3** General structure of prokaryotic genes, where a repressor, promoter, and operator act together to control expression of three genes. Repressors, operators, and promoters are binding sites on the DNA where enzymes attach to begin or prevent transcription.**Figure 4** General structure of a eukaryotic gene, including the upstream promoter and enhancer sequences where protein transcription regulators can bind, and the downstream terminator where transcription ends, and where the 3' UTR controls the longevity of mRNA in the cell. Eukaryotic genes are interrupted by exons, which are translated or transcribed, as well as nontranslated introns, which are removed during the process of posttranscriptional modification.

different groups of parasitic Hymenoptera (wasps) have $N = 5$ and $N = 10$, an ant species has $N = 1$ chromosome, many moths and butterflies have $N = 50$ – 80 and a species of fern has $N = 630$!

Eukaryotic genes contrast sharply with prokaryotic genes in both structure and regulation of expression (Figure 4). First, while several prokaryotic genes are grouped together under control of a single promoter, each eukaryotic gene is expressed individually under control of a promoter specific to that gene. Second, eukaryotic genes are often interrupted, with nontranslated introns interspersed between exons that are translated into proteins. The result is that after transcription, introns are excised and the pieces are spliced back together as a mature mRNA for translation into proteins. The number of

introns can be vast. The human titin gene encodes a long, elastic protein that occurs in the sarcomeres of muscle and has 234 exons, the longest single exon (17,106 nucleotides), and the longest coding sequence (80,781 base pairs = 26,927 amino acids). The longest primary transcript in humans is from the dystrophin gene (2.4 million base pairs).

One consequence of posttranscriptional modification is that the same gene can be spliced into several different mature mRNAs by including or removing different exons. A classic example is the development of gender in animals by alternative splicing and cascades of gene expression leading to male versus female characteristics (Hodgkin, 1990; Marin and Baker, 1998). In *D. melanogaster*, for instance, the male and female forms of the gene *Doublesex* both have the first three

exons, but differ in the particular 3' exons included after splicing.

Eukaryotic gene expression is regulated by transcription factors that bind to promoters and enhancers. Transcription requires the binding of RNA polymerases and protein transcription factors to a promoter, a DNA sequence on the 5' end of the gene, to form a transcriptional complex. Many eukaryotic promoters, but by no means all, contain a TATA box (sequence TATAAA), which typically lies within 50 bases of the transcriptional start site. Another common example is the E-box sequence CACGTG. Enhancers are DNA sequences that function to increase transcription of a gene over basal level, and are usually responsible for tissue-specific gene transcription. Specialized transcription factors bind to the enhancer sequence and transcriptional complex, and are regulated by whether the genes coding for the enhancer have been expressed, by environmental signals, and by signals from other cells. Transcription factors can be classified according to the structure of their DNA binding domains; these include zinc finger proteins, helix–turn–helix proteins, leucine zipper proteins, helix–loop–helix proteins, and steroid receptors.

Once, transcribed, mRNAs carry terminal sequences in the 3' untranslated region (3' UTR) that predetermine their life span in the cell, and in turn regulate how much of a protein is produced. The sequence AUUUA in the 3' UTR is a signal for early degradation, and the more often that this sequence occurs, the shorter will be the life span of the mRNA.

Another common feature of eukaryotes is gene duplication. Some genes that are important for basic housekeeping, like rRNA, may have hundreds or thousands of copies of the gene within the genome, which results in functional redundancy within the genome. Another form of duplication is represented by genes coding for blood proteins (globins) in vertebrates. These gene families include several kinds of duplications, where gene clusters code for a diversified set of proteins that are part of fetal blood versus adult blood on the one hand, and a series of nonfunctional pseudogenes on the other.

Noncoding Repetitive DNA Sequences

Large portions of the genomes of eukaryotes and some prokaryotes consist of repetitive DNA, which is mostly untranscribed and consists of tandemly arranged sequences with identical nucleotide composition. Each DNA sequence can be repeated up to several million times within the genome. Some repetitive DNA is tied up in the heterochromatic parts of the genome that make up the structural elements of chromosome such as centromeres (where sister chromatids bind during cell division) and telomeres (the ends of chromosomes). Otherwise, repetitive DNA may be interspersed throughout the genome. Repetitive elements can be very large (> 10,000 nucleotides) or of moderate size (100–800 nucleotides), but the majority of highly repetitive sequences consists of repeats smaller than 100 nucleotides. Generally speaking, repetitive DNA makes up as little as 10% (fruit fly), and as much as 90% (humans) of eukaryotic genomes, and much of the repetitive DNA is now thought to arise as a by-product of transposable elements moving within genomes (Li, 1997).

Repetitive DNAs are highly variable in number and location among individuals in a population, and are generally classified according to the size of the repeat unit, the number of repeat units per array, and the genomic location of the tandem arrays. No consensus for classifying simple tandem repeats currently exists, and terminology varies among authors. The term “microsatellite” (also simple sequence repeat (SSR)) denotes any tandem array of repeats with a unit length of 2–5 nucleotides. The most common human microsatellites are dinucleotide arrays of (CA)_n, which means *n* repeats of CA. The human genome has ~50,000 (CA)_n arrays, or one array every 30,000 nucleotides. It has been estimated that there are 300,000 trinucleotide and tetranucleotide microsatellites in the human genome or, on average, one array in every 10,000 nucleotides of genomic DNA.

Microsatellites are used extensively in population genetics, DNA fingerprinting for forensics or paternity analysis, and genome mapping. Because a large number of alleles are usually found at each microsatellite locus, a collection of several microsatellite loci can lead to a huge number of possible combinations or DNA profiles. This feature makes these loci useful for identity analysis and forensics. For example, in the investigation of a crime where a biological specimen has been obtained from the crime scene, DNA from the specimen and from a suspect is typed for size at several unlinked microsatellite loci. If the profiles do not match, the suspect is excluded. If they match, the probability of this match occurring by chance can be calculated from the frequencies of alleles in the population. This probability is usually extremely low because of high polymorphism at microsatellite loci. When primers for microsatellites are well designed, and when each pair of microsatellite primers amplify only a single locus, the high polymorphism makes them very useful for genetic mapping, studies of population structure, detecting loss of heterozygosity, and studies of behavior.

Organelles and their DNA

The most likely origins of organelles within the cells of eukaryotic organisms are ancient bacteria or blue-green algae taken up as endosymbionts into the cells of early eukaryotes. The strongest line of evidence for an endosymbiotic origin is that organelle genomes closely resemble those of prokaryotes, both in general and in the details of DNA sequences within genes. As in prokaryotes, organelle genomes are circular double-stranded molecules with little repetitive DNA. Additionally, organelle genes do not contain introns, are transcribed as a group (polycistronically), and have relatively simple prokaryote-like promoters (Mayfield *et al.*, 1995). Although organelles carry out their own transcription and translation, gene expression and regulation in organelles depend upon transcription factors that originate from nuclear genes.

Mitochondrial DNA in Animals

The animal mtDNA is a single circular, double-stranded DNA molecule that ranges in size from 14,000 to 42,000 base pairs.

With few exceptions, the animal mitochondrial genome contains 37 genes that encode 13 protein subunits, 22 tRNAs, and a small and a large ribosomal subunit RNA. Several compilations of primers that are useful for polymerase chain reaction (PCR) amplification of segments of the mitochondrial genomes of animals are currently available (Avisé, 2004; Simon *et al.*, 1994; Palumbi, 1996; Roehrdanz and Degrugillier, 1998).

The analysis of mtDNA has become one of the most powerful tools for studying animal populations. The mitochondrial genome is maternally inherited as a haploid genome: it does not recombine, and it mutates at a faster rate than the nuclear genome in most animal groups. Sequence differences arising from mutations in mtDNA haplotypes (haploid alleles) record the phylogenetic histories of female lineages within and among species. Variation in frequencies of different mtDNA haplotypes can be used to estimate effective migration rates among populations, and the genetic diversity within and among populations. This level of variation is also used for estimating phylogenetic relationships among recently evolved taxa. A number of other unique attributes distinguish animal mtDNA, including within-individual homoplasmy (predominance of a single mtDNA sequence) despite between-individual sequence differences and the rapid pace of nucleotide substitution. Although inheritance of animal mtDNA is usually maternal, it is biparental in some mollusks.

Plant mtDNA

Plant mtDNA is extremely different from animal mtDNA, which has prompted several investigators to suggest independent symbiotic origins. The mtDNA genome in plants ranges from 200,000 to 2,400,000 nucleotides in circumference, and typically exists as a collection of different-sized circles arising from extensive recombination within individuals that convert between a “master” allele and subgenomic circles. Inheritance is not always maternal. Although plant and animal mtDNAs are similar with regard to gene content and general function, their evolutionary patterns differ. Plant mtDNA appears to evolve rapidly with respect to gene order, but slowly in nucleotide sequence (perhaps 100-fold slower than animal mtDNA). Reasons for the slow mutation rate are not understood, but plant mtDNA may have relatively error-free DNA replication, or perhaps highly efficient enzymes for repair of DNA damage. The lack of nucleotide-level variation and regular recombination has limited the utility of plant mtDNA in population genetics.

Chloroplast DNA

Chloroplast DNA (cpDNA) in photosynthetic land plants is also a circular genome, which varies in size from about 120,000 to 247,000 nucleotides, largely because of a large inverted repeat that includes genes for the rRNA subunits. Each chloroplast contains from about 22 to 900 cpDNA copies and each encodes 123 genes. These include four genes for rRNA, 20 genes for ribosomal proteins, 30 genes for tRNAs, many of the photosynthetic proteins, six of the nine genes for ATPase, and chloroplast RNA polymerase. Unlike mtDNA, 15

of the cpDNA genes contain introns. Most chloroplast proteins are encoded by the nucleus, chloroplast ribosomes consist of 52 proteins but only 19 of them are encoded by plastid genome.

cpDNA is transmitted maternally in most flowering plants, biparentally in a few, and paternally in gymnosperms. cpDNA genes have been shown to transpose to the nucleus and there is good evidence that mtDNA, cpDNA, and nuclear genomes exchange genes. The rate of cpDNA evolution generally appears slow both in terms of primary nucleotide sequence and in terms of gene rearrangement. Because of the large size of the cpDNA genome, most systematic treatments have involved restriction site or sequence determinations for particular genes or have monitored the taxonomic distributions of unique cpDNA structural features across higher-level plant taxa. Nonetheless, some studies have uncovered considerable intraspecific cpDNA variation as well, and this suggests that portions of the cpDNA should be useful in population genetics. Again, several primers for amplifying cpDNA genes in a number of plant species are available (e.g., *ndhF*: Olmstead and Sweere, 1994; *rbcl*: Palumbi, 1996).

Mutation

Mutation is the ultimate source of genetic variation, and is generally defined as any change in genetic material, whether phenotypic effects caused by the mutation are large, small, or nondetectable. The causes of mutation include direct insults from environmental effects like ultraviolet light, chemicals, X-rays and other atomic particles, but many mutations arise from errors in DNA replication and DNA repair during cell division. RNA viruses, in fact, depend upon error-prone RNA polymerases to generate novel variants during every replication of the viral genome.

One class of mutations arises from gross changes at the level of chromosomes, where chromosomes break and are then modified by deletions, insertions, inversions, translocations, and duplications (Table 2). Although the term “chromosome” is used here, similar mutations occur in the genomes of prokaryotes as well. Chromosomal mutations can result in changes in the total amount of DNA found within and among different species, and in the case of gene duplications or deletions, can change the number of genes. Mutations like these can have drastic phenotypic effects. Individual genes can be disrupted if insertions occur within them, or if part of a gene is lost in a deletion. Transposable elements can cause deleterious mutations by inserting themselves into genes.

Inversions of chromosomal fragments, where a fragment is flipped 180° from its original orientation and reinserted at the same place, will cause complex looping of the chromosomes when they pair during meiosis and will reduce recombination. Inversions are common in some organisms, like the Diptera, especially fruit flies, blackflies, and malaria mosquitoes.

Translocation of pieces of chromosomes from one place to another within the genome will result in a change in the size or number of chromosomes. The effects of translocations can be dramatic, often resulting in sterility because of the inability of the altered chromosomes to pair during meiosis. Thus,

translocations are a potential mechanism of isolation of a single species into incompatible breeding groups, and eventually the formation of new species.

The magnitude of phenotypic effects of duplications depends on the size of the affected chromosomal fragment, and thus the number of genes that are duplicated. An example is trisomy 21, which results in Down syndrome (mental retardation, flat facial features, and heart defects). Trisomy results from a failure of proper segregation of chromosomes during meiosis so that one gamete contributes two complete copies of chromosome 21, resulting in three copies in the zygote. On the other hand, duplications are an integral part of the evolution of multigene families, like the various globin genes and nonfunctional pseudogenes in vertebrates. Duplication is the main mechanism by which entirely new genes arise (Li, 1997).

Mutations can also occur at the level of single-nucleotide changes, including some that affect the reading of the genetic code (Table 2). Single-nucleotide substitutions are classified as transitions if they occur between similar nucleotides, between purines (A ↔ G) or pyrimidines (C ↔ T), and transversions if mutations substitute purines for pyrimidines and vice versa (e.g., A ↔ T). This distinction is important because the transitions are much more common than transversions, sometimes occurring 20 times more frequently. Further examination of the genetic code (Table 1) reveals that where a substitution occurs within a codon will determine the severity of the mutation. Most mutations in the first nucleotide position will result in an amino acid change (missense) or a mutation to a stop codon (nonsense). Mutations at the second position always result in a change (missense and nonsense). Third-position mutations are usually synonymous ("silent"), resulting in no change of amino acid. Nucleotide insertions and deletions will result in a shift of the "reading frame," so that all amino acids are changed after the mutation.

Mutations occur at very low rates, and are usually measured as the number per meiosis in eukaryotes, or as the number per cell division for prokaryotes. The numbers of new mutations are commonly <1 in 10,000 (10^{-4}) for nucleotide substitutions, and are as low as 1 in 100,000,000 (10^{-8}) for some visible mutations like coat colors. In an evolutionary sense, mutation is considered a very slow process. Mutation can still produce considerable variation within populations

because the numbers of new mutations produced in each generation in a population will be a function of population size. In addition, if the number of genes in a genome is taken into account, even low mutation rates can generate high numbers of new mutations in each individual within a population.

Glossary

Electrophoresis Separating charged molecules (such as polypeptides or polynucleotides) between the two poles of an electric field.

Genome A complete single set of genes of an organism or organelle; also the basic haploid chromosome set.

Genomics The study of the molecular organization of genomic DNA and physical mapping.

Heterozygosity The average number of different heterozygotes across loci divided by all loci studied.

Polymorphism Different alleles at a gene locus within a population.

Genetic diversity (i.e., molecular hereditary differences within or between populations) is the basis of evolutionary change. The nature of genetic diversity among organisms has always been the basic problem of evolutionary genetics (Darwin, 1859; Lewontin, 1974; Kimura, 1983) as well as of domestication, agriculture, and medicine. However, despite its cardinal role in evolutionary theory and application, the maintenance of genetic diversity remains largely enigmatic, notwithstanding the dramatic discoveries of molecular biology, which revealed abundant genetic diversity in nature.

The Problem

Historical Background

The era of molecular evolution was ushered in by three major discoveries in the late 1950s and 1960s: (i) recognition by Markert and Moller in 1959 of molecular diversity of enzymes and their importance in genetics, physiology, development, and evolution; (ii) Identification by Zuckerkandl and Pauling in 1965 of protein sequence variation between species and the resulting postulate of the molecular clock; and (iii) evaluation in 1966 of enzyme variation (isozymes and allozymes) in *Drosophila* by Lewontin and Hubby and Johnson *et al.* and in humans by Harris. Molecular biology permitted the characterization of genetic diversity among individuals, populations, and species—the three cornerstones of evolution. It did so first by unraveling relationships between genes and proteins (Lewontin, 1974). Second, it did so by elucidating, at the extranuclear and nuclear coding and noncoding DNA regions, the structure, expression, function, mechanism, and evolution of genes, intergenic spacers, and multigene families by employing recombinant DNA methodologies (Watson *et al.*, 1987; Avise, 1994).

Advancements in molecular evolution have followed the introduction of new laboratory techniques (Avise, 1994). Among the most influential methods have been protein electrophoresis in the late 1960s and 1970s, restriction fragment length polymorphism (RFLP) analyses of nuclear and mtDNA in the late 1970s and 1980s, DNA fingerprinting in the mid to late 1980s, and polymerase chain reaction (PCR)-mediated

DNA sequencing in the 1990s. Comparative genomics and genome prospecting (*Science* 286, October 15, 1999) promise to highlight the genetic basis of evolutionary change and the nature, expression, meaning, transfer, and regulation of information in biological systems, thus unraveling the blueprint and evolutionary forces driving life.

The Enigma of the Maintenance of Genetic Diversity

Early and later molecular-genetic studies revealed massive levels of genomic diversity, surpassing any prediction. In addition, a comprehensive compilation of dense genetic maps was published of viruses, bacteria, plants, animals, and humans. In 1998, Deloukas *et al.* physically mapped 30,000 encoded human genes for proteins of known functions. The ongoing human genome project (HGP), the largest biological project ever (Bodmer and McKie, 1994), ushered in a new era in the life sciences in which complete genomes of prokaryotes (Casjens, 1998) and eukaryotes became available. Genetic maps, current complete genome sequences and those expected in the near future, and tens to hundred of thousands of protein and DNA sequences have contributed dramatically to elucidating genome diversity, organization, expression, dynamics, and evolution (Karlin *et al.*, 1998). They form the basis for future studies of genetic diversity, when more genomes within species will be analyzed.

However, despite the ease of measuring and deciphering genetic diversity and the dramatic advances in comparative genomics, the evolutionary forces that generate and maintain segregating genetic diversity, preventing allele fixation or random elimination in nature, remain elusive.

Theories of Molecular Evolution: Selection versus Neutrality

Theoretically, balancing selection could account for protein polymorphism (Gillespie, 1991). In contrast, the neutral theory of molecular evolution (Kimura, 1983) suggests that most of the molecular-genetic diversity within and between species is neutral (i.e., non-selective) or “non-Darwinian.” The neutralist–selectionist debate has been one of the major controversies in evolutionary biology since the late 1960s. How much of the genetic diversity at single and multilocus

structures is adaptive, processed by natural selection and contributing to differences in fitness? The problem of distinguishing between deterministic and stochastic forces in evolution has pervaded evolutionary biology at all levels, genotypic and phenotypic, and is now focused on DNA polymorphisms. I recognize the contribution of the neutral and nearly neutral theories of molecular evolution, primarily by representing a null hypothesis to selection. Nevertheless, by ignoring the ecological heterogeneity and stress in evolution, neutral and nearly neutral theories have stripped genetic diversity from nature. I believe that in-depth understanding of genetic diversity in nature is intimately linked to the interface between ecology and genetics; hence, to ecological genetics and now to ecological genomics. I submit that only this essential interface can meaningfully highlight the dynamic evolution of genetic diversity in nature.

The Structure of This Review

This review comprises three unequal perspectives of molecular-genetic diversity of protein and DNA in nature: methodology, evidence, and theory. The main focus is on the huge amount of protein and DNA evidence from nature in diverse groups of organisms across phylogeny from bacteria to humans and across diminishing geographical scales (global, regional, and local). The evidence naturally leans heavily on results of genetic diversity in plants and animals obtained during the past 25 years at the Institute of Evolution, University of Haifa, Israel, that demonstrate the pervasiveness of ecological determinants in genetic differentiation. In theory too, I focus on theoretical results obtained during the past decade at the Institute of Evolution that show how selection in cyclical environments can maintain genetic polymorphism in nature, thus preventing drift. I mainly refer to books which cite the primary literature.

Methodologies

The methodologies analyzing protein and DNA diversity have been extensively described (Lewontin, 1974; Avise, 1994; Mitton, 1997), so they are only briefly reviewed here.

Protein Polymorphism

Technical Innovation

New techniques at the protein level permit an increasingly subtle resolution of allelic variation at a locus. These techniques include isoelectric focusing in various media; high-resolution, two-dimensional electrophoresis; thermal and urea denaturation analysis; and sequential gel electrophoresis (SAGE), in which electromorphic classes were retested with other pHs, buffer systems, and gel pore sizes (Ramshaw *et al.*, 1979).

Hidden Variation

"Alleles" detected by routine gel electrophoresis are essentially phenotypes or "electromorphs" (i.e., internally heterogeneous,

genetically involving "hidden variation"). For example, xanthine dehydrogenase has many more alleles than are visible routinely (Ramshaw *et al.*, 1979). Recent pulsed-field gel electrophoresis for separating large DNA fragments, recombinant DNA techniques, methods of genomic "hopping," and new DNA sequencing strategies and genomic analysis reinforce the powerful field of molecular evolution, climaxing in the HGP (Bodmer and McKie, 1994). Extensive comparative analyses across genomes of model organisms (Karlin *et al.*, 1998) became the focus of genomic and proteomic studies, highlighting diversity in nature (Avise, 1994). These new horizons partly unraveled the molecular structure, function, and evolution of life. Bioinformatics became increasingly important as many genes and genomes became analyzable. Comparative genomics, using dense genetic maps based on coding genes and on microsatellite and single nucleotide polymorphisms (SNPs), permit precise gene homolog alignment across taxa, the unraveling of gene function and regulation, highlighting of genome organization and evolution, and the determination of the genetic basis of speciation and adaptation.

DNA Polymorphism

RFLP, PCR, and Mini- and Microsatellites

Many assays reveal DNA diversity (Avise, 1994). Before the revolutionary PCR was established, DNA fingerprinting technology had been revolutionized by RFLP analysis, a very efficient technique but quite laborious and not suitable for high-throughput applications. Hundreds of restriction enzymes, originating in bacteria, cleave duplex DNA at particular oligonucleotide sequences, usually 4–6 base pairs (bp) in length. Since its development, PCR has been a powerful tool for DNA fingerprinting and for effectively measuring genetic diversity within and between populations. These molecular markers include minisatellite, also called variable number of tandem repeats (VNTR), consisting of core sequences 10- to 15-bp long and extending from 16 to 64 bp, and microsatellites (2–6 bp), also called simple sequence repeats (SSRs) (Goldstein and Schlotterer, 1999). Microsatellites and minisatellites differ in size, mutation processes, and chromosomal distribution, but the boundary between the two classes is not defined.

Random Polymorphic DNA

A novel PCR-based strategy involving the use of arbitrary primers (AP-PCR) to amplify random polymorphic DNA (RAPD) fragments has been developed using short primers (≈ 10 bp). RAPDs generate polymorphic markers using very small amounts of starting DNA or RNA, independently of any prior knowledge of the target DNA sequence. This feature makes RAPD a useful tool in genetic analysis. Compared with protein polymorphisms, DNA markers reveal more genetic diversity and permit choice among sets of loci with different functions and patterns of inheritance (Mitton, 1997; Avise, 1994). Use of molecular markers dramatically widened the perspectives of evolutionary biology (Avise, 1994).

Amplified Fragment Length Polymorphism: A New, Powerful Technique for DNA Fingerprinting

A major novel DNA fingerprinting technique called amplified fragment length polymorphism (AFLP) was recently described. AFLP is based on the selective PCR amplification of restriction fragments from a total digest of genomic DNA. AFLP can analyze genetic diversity in many hundreds of genes in both coding and noncoding regions across the genome if several enzyme combinations are applied, allowing high-resolution genotyping of fingerprinting quality. The time and cost efficiency, replicability, and resolution of AFLPs are superior or equal to those of other markers (allozymes, RAPD, RFLP, and microsatellites), except that AFLP methods primarily generate dominant rather than codominant markers.

Nucleotide Polymorphism

Studies of nucleotide polymorphism have three distinct advantages: (i) detection of all types of sequence changes (single nucleotide substitutions, insertion/deletions, and copy number variation in nucleotide repeat motifs), of which SNPs are the most common; (ii) variant detection in coding (cSNPs and noncoding DNA; and (iii) combined detection and genotyping using a single method.

Summary

DNA techniques revealing DNA diversity include RFLP, RAPD and AFLP, mini- and microsatellites, SNP and sequencing; all are relevant for analyzing DNA diversity. PCR is currently the method of choice for amplifying DNA segments for detecting polymorphism. Generally, DNA diversity is higher than protein diversity (see Figure 4).

Comparative DNA Analysis across Diverse Genomes

The era of comparative genomics is dramatically advancing (Casjens, 1998; Karlin *et al.*, 1998; *Science*, October 15, 1999), including the analysis of complete genomes for various organisms and imminent completion of the HGP. Genes, individuals, and species are becoming comparable. Sequence polymorphism will highlight the generation, maintenance, and function of genetic diversity responsible for controlling normal development, physiologic homeostasis, and disease processes. This information explosion will revolutionize molecular evolutionary studies. Comparative analysis of complete genomes includes assessments of genomic compositional contrasts based on di-, tri-, and tetranucleotides relative abundance values; identification of rare and frequent oligonucleotides; evaluations and interpretations of codon biases in several large prokaryotic genomes; and characterizations of compositional asymmetry between the two DNA strands in certain bacterial genomes. Comparative analysis also allows identification of alien (e.g., laterally transferred) genes and detection of potential specialization islands in bacterial genomes and the assessment of DNA curvature. It can compare genomes within species and across life and cluster organisms according to linguistics based on many words in large DNA stretches.

Microarrays: Biotechnology's Discovery Platform for Functional Genomics

Advances in microarray technology make possible massive parallel mining of biological data, based on PCR, with biological chips providing hybridization-based expression, monitoring, polymorphism detection, and genotyping on a genomic scale, as reported by Schena *et al.* (1998). Microarrays containing sequence representative of all the genes of an organism may soon permit the expression analysis of the entire human genome in a single reaction. These "genome chips" will provide unprecedented access to genomic diversity of many thousands of genes to large-scale gene discovery as well as polymorphism screening and mapping of genomic DNA clones on a massive scale—critical for science and application in agriculture and medicine. Oligonucleotide microarray (DNA chip)-based hybridization analysis is a promising new technology which potentially allows rapid and cost-effective screens for all possible mutations and sequence variations in genomic DNA. Currently, it is performed in humans, mice, and *Arabidopsis*, but use in additional species has been reported. The increasing use of relatively inexpensive microarrays is expected to revolutionize genomic, proteomic, and other biological research projects.

Encyclopedia of Genes

Extensive ongoing programs in plants and animals are generating a large database of expressed sequence tags (ESTs) that can provide rapid access to numerous genes and their diversity. The development of a comprehensive database of ESTs for *Arabidopsis*, corn, soybean, rice, barley, wheat, mouse, and human has been reported. As of October 23, 1998, 352,040 sequences had been generated in the mouse and annotated and deposited in dbEST, in which they comprised, according to Marra *et al.* (1999), 93% of the total ESTs available for the mouse. EST data are versatile and have been applied to gene identification, comparative sequence analysis, comparative gene mapping and candidate disease gene identification, genome sequence annotation, microarray development, and the development of gene-based map resources. Large-scale exploration of the genic diversity of the genome is becoming possible through the UniGene database (<http://www.ncbi.nlm.nih.gov/UnGene>).

Evidence: Genetic Diversity Within and Among Species

Protein Diversity

Electrophoretic results have revealed large amounts of genic polymorphism in natural populations (Lewontin, 1974; Nevo, 1978, 1988, 1998; Hamrick *et al.*, 1979; Nevo *et al.*, 1984; Avise, 1994; Mitton, 1997). This is true for both eukaryotes and prokaryotes. Currently, theory appears to lag behind evidence. The review and reanalysis of approximately 1100 plant and animal species (Nevo *et al.*, 1984) revealed an average heterozygosity, H , of 0.073 (SD 0.076) and an average proportion of loci polymorphic, P , of 0.284 (SD 0.197). Across

Figure 1 Levels of genetic (allozymic) diversity among higher taxa based on a mean of 23 gene loci per species, in 1111 species. *Hatched region indicates parthenogenetic species (reproduced from Nevo E, Beiles A, and Ben-Shlomo R (1984) The evolutionary significance of genetic diversity: Ecological, demographic and life history correlates. In: Levin S (mang. ed.) *Lecture Notes in Biomathematics* and Mani GS (ed.) *Evolutionary Dynamics of Genetic Diversity*, vol. 53, pp. 13–213. Berlin, Heidelberg: Springer-Verlag).

species, the coefficient of correlation between H and P was $r = 0.793$, $p < 0.001$. These estimates are based on the average of 23 electromorphically detectable gene loci (minimum 14 loci) and an average of 199 individuals per species (minimum 10 individuals) (Figure 1). This set of data was assembled up to 1983, and many hundreds of species have since been tested (see Figure 2.2 in *Awise, 1994*, that summarizes heterozygosity estimates of 1803 species: 648 vertebrate, 370 invertebrates, and 785 plant species), all demonstrating diverse levels of polymorphisms (Mitton, 1997). Genetic diversity varies dramatically among species. Fruit flies, marine mussels, and conifers have much genetic diversity, whereas large vertebrates have much less (Mitton, 1997).

The aforementioned genetic indices appear to be lower than the real ones since routine horizontal gel electrophoresis underestimates diversity and protein coding genes represent only a small portion of the genome. Regarding levels of diversity, protein diversity does not represent the noncoding genome, which amounts to 90–98%, involving invariant and variant portions whose general diversity levels in natural populations appear to be high. Studies of “hidden variation” indicate that most protein diversity is detectable (Ramshaw *et al.*, 1979), thus increasing H of enzymatic loci. Moreover, at the DNA sequence level of individuals, most loci may prove heterozygous. Nevertheless, there are significant merits to the estimates of H and P , derived from routine protein electrophoresis. First, although relative, low, and limited genomically, they are commensurate estimates of genetic diversity among numerous populations and species living in varied ecologies. Second, H and P are highly correlated in global (Nevo *et al.*, 1984) and regional (Nevo, 1988, 1998) analyses. Thus, although hidden variation is regrettably lacking in studies of routine protein electrophoresis, in most species the high correlation of H and P makes for a profitable analysis since P is largely independent of the high resolution

achievable by SAGE and other new techniques. Third, the relatively large number of electromorphic protein loci currently available in *Drosophila* and the many species analyzed permit a sound statistical analysis of isozyme phenotypes in an ecological context rather than only in genetic terms (Nevo *et al.*, 1984; Nevo, 1978, 1988, 1998).

The Adaptive Evolution of Enzyme Kinetic Diversity

Kinetic studies of hemoglobin, haptoglobin, and transferrin proteins and at least a dozen enzyme polymorphisms typically reveal biochemical kinetic differences among the gene products of alternative genotypes at a locus (Mitton, 1997). These include single gene effects such as lactate dehydrogenase in killifish, leucine aminopeptidase in blue mussel, and phosphoglucose isomerase (PGI) in *Colias* butterflies. In the latter, Watt and colleagues discovered in the 80s that PGI heterozygotes fly over a greater range of temperatures and produce 33% more eggs. Additional examples are alcohol dehydrogenase (ADH) in fruit flies, salamanders, and barley; glutamate pyruvate transaminase in cope-pods; and esterase, glucose-6-phosphate, 6-phospho-gluconate dehydrogenase, and superoxide dismutase in fruit flies. In all these cases, biochemical-kinetic studies reveal differences among phenotypes, either within or between species, that have measurable effects of alternative genotypes on the physiology of whole individuals. They result in fitness differences distinguished by natural selection in accord with their alternative spatiotemporal environments (Mitton, 1997). Usually, the heterozygotes are intermediate between homozygotes, but sometimes molecular overdominance for enzyme kinetics is found.

Patterns of Variation Among Loci

Proteins vary genetically. Regulatory enzymes appear to be more variable than nonregulatory enzymes, and enzymes that work on many substrates appear to be more variable than

enzymes that utilize a single substrate. Genetic diversity tends to decrease from monomer to dimer to tetramer as the steric restrictions on the molecule increase. The number of alleles at a locus and the heterozygosity at a locus tend to increase with the subunit size of the protein.

Genetic Population Structure

Geographical clines may reflect the action of natural selection on genetic polymorphism at local, regional, and global scales. In *Drosophila melanogaster*, several latitudinal clines occur for many characters such as allozymes, inversions, and quantitative traits. The identical nature of these clines on the various continents, in both the Northern and Southern Hemispheres, strongly suggests adaptation to specific stress factors, primarily climatic selection. Polymorphism for stress-resistance genes abounds in natural populations. The ADH polymorphism shows high frequencies of the S allele in tropical regions and this declines with latitude. The reasons for this cline are difficult to determine because of the entanglement with other polymorphisms varying with latitude. In 1977, Van Delden and Kamping reviewed the tentative connections with other polymorphisms such as α -GPDH, in (2L)t inversion, body size, and development time with respect to the possible environmental stress factors involved. They concluded from these results, and also from recent experiments, that the (2L)t plays a dominant role in resistance to high temperature and is partly responsible for the ADH cline. They are currently studying the specific selective forces acting on ADH, focusing on the physiological and life history aspects. Many plant and animal species distributed in several climatic zones—tropical, temperate, and arctic—display a decline in gene diversity, both allozyme and DNA, towards the Arctic (Nevo *et al.*, 1984). This is highlighted by postglacial colonizing populations. Regional and local clines also abound in nature.

Partition of Genetic Diversity

An important analysis is that of genetic partition within and between populations. In most analyzed outcrossers, genetic diversity is chiefly within populations (e.g., 85% in humans). In contrast, in some selfers (e.g., wild emmer wheat) only 40% of genetic diversity is within and 60% is between populations. This partition is shaped by both external (gene flow and selection at the population level) and internal (genomic and genic) evolutionary forces.

DNA Diversity

DNA technologies revolutionized population genetics by providing an unprecedented amount of genetic diversity for critical analysis and hypothesis testing. I briefly review these dramatic developments, from molecular (extranuclear, mitochondrial, chloroplast, and nuclear) DNA markers to sequence polymorphism.

MtDNA Diversity

MtDNA is largely maternally nonrecombiningly inherited and demonstrates a rapid pace of evolution and an extensive high level of intraspecific restriction. PCR and sequence polymorphism derive primarily from base substitution with a

preponderance of transitions, length variation, sequence rearrangements, and duplications of coding sequences (Avice, 1994). Hence, its relevance is not only to large-scale phylogenies but also to micro-geographic divergence, i.e., to intraspecific phylogeography, the recently established bridge between population genetics and systematics. The amount of mtDNA polymorphism within species and sequence heterogeneity is striking. Remarkably, a different scenario emerged for plant mtDNA from that in animals. Whereas animal mtDNA ranges in size from 14 to 26 kb in length, that of plants (e.g., maize) is approximately 30 times larger. Most polymorphism in plant mtDNA is attributable to major reorganizations of sequence. The level of mtDNA polymorphism in higher animals is several-fold higher than that of single-copy nuclear DNA. The maternal inheritance and high polymorphism of mtDNA and the assay of whole mtDNA by long PCR provide unique opportunities for population evolutionary studies of animals and plants on both micro- and macrogeographic scales. They contribute to natural history, population structure and signature, gene flow, hybridization, biogeography, phylogeny, and biological conservation.

Mitochondrial genomes are increasingly being used to study ancient divergences among animal groups. Recent studies by Curde and Koder (1999) of complete mitochondrial DNA sequences reached somewhat heretical conclusions, raising questions about the use of mitochondrial gene sequences for studying the relationships among highly divergent lineages. Other studies have documented convergent evolution of mitochondrial gene order, casting doubt on the use of these characters for phylogenetic analysis. The use of mitochondrial genomes for studying such deep divergences is coming under increased scrutiny, and these novel results need to be confirmed with data from nuclear genes.

Comparative Summary of Genetic Distances in the Vertebrates from the Mitochondrial Cytochrome b Gene

Mitochondrial cytochrome b is among the most extensively sequenced genes to date across the vertebrates. Johns and Avice (1998) employed approximately 2000 cytochrome b gene sequences from GenBank to calculate and compare levels of genetic distance between sister species, congeneric species, and confamilial genera within and across the major vertebrate taxonomic classes. The results of these analyses parallel and reinforce some of the principal trends in genetic distance estimates derived from multilocus allozymes. In particular, surveyed avian taxa on average show significantly less genetic divergence than do same-rank taxa surveyed in other vertebrate groups, notably amphibians and reptiles.

Chloroplast Genome Comparisons

Chloroplast genome (cpDNA) evolution is also very dynamic, indicating gene transfer to the nucleus. Among the 210 different protein-coding genes contained in the completely sequenced chloroplast genomes from a glaucocystophyte, a rhodophyte, a diatom, an euglenophyte, and five land plants, Martin and colleagues identified in 1998 the set of 45 genes common to each and to a cyanobacterial outgroup genome.

Phylogenetic influence, with an alignment of 11,039 amino acid positions per genome, surprisingly indicates that independent parallel gene losses in multiple lineages outnumber phylogenetically unique losses by more than four to one. They identified homologs of 44 different plastid-encoded proteins as functional nuclear genes of chloroplast origin, providing evidence for endosymbiotic gene transfer to the nucleus in plants. cpDNA diversity in lodgepole pine was high within populations, with little (> 5%) differentiation among populations, in contrast to the mtDNA pattern as shown by Hamrick and Godt in 1990 (as cited in Mitton, 1997, p. 71). Extensive intraspecific cpDNA diversity may sometime exceed interspecific diversity, reflecting dynamic ecologies and seriously affecting phylogenetic conclusions, as in the pine *Draba* species.

Simple Sequence Repeats (SSRs)

SSRs consist of tandem repeats of relatively short nucleotide motifs, such as TCCTCTCTCTCC. Microsatellite repeat number can range from two (TA)₂ or three (GA)₃ to a few dozen (GCAA)₁₁, whereas minisatellites often consist of many dozens or even hundreds of repeated motifs. Significantly, SSRs experience mutation at notably higher rates than do nonrepetitive sequences: 10⁻² to 10⁻³ per locus, per gamete, per generation, which leads to their high polymorphism. Replication slippage, sister chromatid exchange, unequal crossing-over, and gene conversion may cause microsatellite diversity. Replication slippage seems to play a major role in producing new alleles at microsatellite loci (Goldstein and Schlotterer, 1999). SSRs are characterized by high site-specific and reversible rates of gain or loss in the number of tandem repetitions of a short DNA motif. Importantly, recent critical population genetics and specific chromosome data derived from Li and colleagues in 1999 at our laboratory indicate massive genomic non-random chromosomal and environmental distributions of microsatellites, suggesting that they are subjected to natural selection, generating adaptive complexes in contrast to neutral theory expectations.

The functional properties of SSRs suggest evolution's effect on mutability, as recently concluded by King and Soller (as cited in Wasser, 1999). Many SSRs are functionally integrated into the genome and exert a quantitative regulatory effect on gene transcription activity affecting phenotype and fitness. Genes associated with SSRs may be favored by indirect selection whenever quantitative variation in the affected traits can provide a population with genetic resilience for adaptation, especially in stressful, fluctuating, or heterogeneous environments. Such "adjustable genes" may provide a prolific and evolutionarily significant source of quantitative genetic variation.

Nucleotide diversity of the human nuclear genome has been estimated to be approximately 0.1%. For two randomly selected sequences, this number translates into one polymorphic site for 1000 nucleotides (or, in a large sequence sample, one polymorphic site is expected for every 200–500). Since the human nuclear genome contains approximately 3 billion nucleotides, several million polymorphic sites are expected to exist.

Single Nucleotide Polymorphism

SNPs are the most frequently found DNA sequence variations in animal and plant genomes, usually followed by SSRs, RAPDs, and allozymes. Recent SNP surveys in humans reported different rates of polymorphism among classes of sites within genes (noncoding, degenerate, and nondegenerate) as well as between genes. Of all coding SNPs, 54% lead to predicted change in the protein sequence. As expected, the coding SNPs that alter amino acid sequence of the encoded protein are found at a lower rate and with lower allele frequencies than silent substitutions. This was interpreted as a reflection of selection against deleterious alleles during human evolution. Determination of ancestral alleles from human SNP polymorphisms became available using high-density oligonucleotide arrays. A densely packed map of human SNP sites could efficiently identify disease-associated genes by linkage disequilibrium between sets of adjacent markers and highlight human history. In plants, SNP polymorphism has been associated with transcript efficiency, nonconsensus splice sites, and gene expression. The following sections discuss the results of genetic diversity and divergence at global, regional, and local scales based primarily on results derived at the Institute of Evolution since 1979.

Global Analysis of Genetic Polymorphisms

Global Allozyme Diversity Across Phylogeny

We used the entire globe as a large-scale ecological genetic laboratory. We analyzed the correlates of biotic factors involving ecological, demographic, and life history variables with the level of genetic diversity in natural populations of animals and plants (Nevo *et al.*, 1984). This review involved 1111 species studied for allozymic variation with an average of 23 gene loci in each species and a biotic profile characterized by 21 variables (7 ecological, 5 demographic, and 9 life history and other biological characteristics). We then (i) estimated the levels of genetic diversity, indexed by heterozygosity and polymorphism, for all species, three major taxa (vertebrates, invertebrates, and plants), 10 different higher taxa, and the categorized 21 biotic factors; (ii) correlated the levels of genetic diversity with the biotic factors; and (iii) matched some of the evidence obtained with theoretical predictions.

The following results were obtained:

1. The levels of genetic diversity vary nonrandomly among populations, species, and higher taxa and also among ecological parameters (life zone, geographical range, habitat type and range, and climatic region) (Figure 2), demographic parameters (species size and population structure, gene flow, and sociality), and life history characteristics (longevity, generation length, fecundity, origin, and parameters related to the mating system and mode of reproduction).
2. Generally, genetic diversity is higher (i) in species living in broader environmental spectra; (ii) in large species with a patchy population structure and limited migration as well as in solitary or social species; (iii) in species with small body size, annuals or long-lived perennials, older in time, with smaller diploid chromosome numbers; and (iv) in plant species primarily out-crossed, reproducing sexually,

Figure 2 Global analysis of genetic diversity: levels of heterozygosity of ecological factors. Numbers in the bars indicate species. Significance NS = $p > 0.05$; * = $p < 0.05$; ** = $p < 0.01$; *** = $p < 0.001$ (reproduced from Nevo E, Beiles A, and Ben-Shlomo R (1984) The evolutionary significance of genetic diversity: Ecological, demographic and life history correlates. In: Levin S (mang. ed.) *Lecture Notes in Biomathematics* and Mani GS (ed.) *Evolutionary Dynamics of Genetic Diversity*, vol. 53, pp. 13–213. Berlin, Heidelberg: Springer-Verlag).

and pollinated by wind. Diversity among species has also been summarized by Mitton (1997). Higher genetic diversity characterizes species with high fecundity, large populations, broad geographic ranges, and a high speciation rate. In contrast, low genetic diversity characterizes endemic species with low fecundity and low speciation rate.

- Genetic diversity is partly correlated and predictable by a three- or four-variable combination of ecological, demographic, and life history variables, largely in that order. Ecological factors account for the highest proportion of the 20% explained genetic variance of all species compared with demographic and life history factors (90, 39, and 3.5%, respectively). Within individual higher taxa, the explained portion of genetic diversity increases considerably (mean of 44% and maximum of 74% in mollusks). Neutrality theory would be substantiated if demographic

variables, rather than ecological variables, could better explain the variation in genetic diversity. The opposite, however, was often found, substantiating selection as an evolutionary driving force of genetic diversity in nature. A more detailed global analysis of genetic differentiation in amphibians was performed in 1991 by Nevo and Beiles and in small mammals across the globe (Nevo, 1999). In both cases, genetic diversity, and in amphibians also genome size, is predictable by ecological factors: The higher the environmental heterogeneity and stress, the higher the heterozygosity. Similar conclusions were drawn for 480 species of plants in 1990 by Hamrick and Godt and for diverse animal species (Mitton, 1997). As expected, theoretically the global evidence exhibits a positive relationship between environmental diversity and genetic diversity, as was also shown in cage experiments. Clearly,

environmental diversity enhances genetic diversity. Levins (1968) predicted that environmental grain determines the level of polymorphism. Finegrained species (highly mobile) would evolve a monomorphic strategy, whereas coarse-grained species (highly sedentary) would maintain polymorphism. This theoretical prediction is largely supported by evidence (Nevo *et al.*, 1984).

The patterns and correlates of genetic diversity revealed in the global analysis for many unrelated species, subdivided into different abiotic and biotic regimes, strongly implicate selection in the genetic differentiation of species. Natural selection in several forms, but most likely through the mechanisms of spatiotemporally varying environments at the various life cycle stages of organisms, appears to be an important evolutionary force causing change at the molecular level. Other evolutionary forces, including mutation, migration, and genetic drift, certainly interact with natural selection, either directly or indirectly, and thereby contribute differentially, according to circumstances, to population genetic differentiation at the molecular level. However, the final orientation of the evolutionary process is determined by natural selection (Bell, 1997).

Regional Analysis of Genetic Polymorphisms

Regional: Allozyme Diversity across Phylogeny in Israel and the Near East

Israel as an Ecological Genetic Laboratory of Increasing Aridity Southwards

Our regional analyses of genetic diversity extended over Israel and the Near East. We used Israel, with its remarkable physical and biotic diversities, as a medium to large-scale ecological genetic laboratory (Nevo, 1988, 1998). In 1988, Nevo and Beiles conducted an ecological test of protein polymorphism in 13 unrelated taxa of plants, invertebrates, and vertebrates involving 21 species, 142 populations, and 5474 individuals (Figure 3), following the extensive studies of allozyme diversity in 38 species in Israel.

Each individual, population, and species were tested, on average, for 27 enzymatic gene loci. These species varied in population size and structure, life histories, and biogeographical origins, but they largely shared geographically short and ecologically stressful gradients of increasing aridity in Israel, both eastward (70 km) toward the Syrian and Jordanian deserts and (mainly) southward (260 km) towards the Negev desert. We found genetic parallelism across most taxa

Figure 3 Parallel genetic patterns in the level of gene diversity, H_e , of 13 enzymatic systems averaged across all taxa studied here. The average regression line is $H_e = -0.0556 + 0.4803 RV$. The only change is that *Gryllotalpa gryllotalpa* has been divided into two species, *G. tali* ($2n = 19$) and *G. marismortui* ($2n = 23$). See Broza *et al.*, 1998, cited in Nevo, 1999. The regression line represents *G. tali* (reproduced from Nevo E and Beiles A (1988) Genetic parallelism of protein polymorphism in nature: Ecological test of the neutral theory of molecular evolution. *Biol. J. Linn. Soc.* 35: 229–245).

and most loci. Observed average heterozygosity, H , and gene diversity, H_e , were positively and overall significantly correlated with rainfall variation, which is lowest in the northwest and highest in southern deserts (i.e., with a wider, fluctuating, climatic temporal niche in the desert) (Figure 3). Similar trends were found for several DNA systems in subterranean mole rats in Israel (Nevo, 1999). This result corroborates the environmental theory of genetic diversity, which regards ecological heterogeneity and stress as major determinants enhancing genetic divergence.

Notably, in the regional Israeli studies, heterozygosity, H , is negatively correlated with effective population size, N_e ; H increases, whereas N_e declines drastically toward the deserts. This contradicts a basic postulate of neutrality theory, which predicts positive correlation between H and N_e (Kimura, 1983). Our results are clearly inconsistent with the genetic drift theory postulated in 1931 by Sewall Wright or the neutral theory of molecular evolution, even in its milder form of near neutrality (Ohta and Gillespie, 1996). Our results suggest that natural selection, through environmental range and stress, in space or time or both appears to be an important genetic differentiating evolutionary force at the protein and DNA levels (i.e., driving molecular evolution) (Nevo, 1998). Similar results were obtained in extensive ecological genetic studies in wild wheat in 1989 by Nevo and Beiles and in subterranean mole rats across the Near East and Asia Minor (Nevo, 1999). Genetic diversity either in the inbreeding wild cereals aboveground or in outbreeding mole rats underground is primarily determined by climatic selection. Similar conclusions—that is, that natural selection on allozyme polymorphism may be intense with selection coefficients in the range of 0.1–0.8—have also been reached for many model organisms (Mitton, 1997). Remarkably, the abundant genetic diversity found in natural populations of plants and animals provides immense genetic resources for crop improvement in agriculture, biotechnology, and gene therapy in medicine.

Genetic Parallelism and Ecological Stress in Subterranean Mammals

Parallel genetic patterns of increasing diversities (primarily southward and secondarily eastward) were shown in 1996 by Nevo and colleagues in Israeli subterranean mole rats for diploid chromosome numbers, nuclear allozyme, mtDNA, RAPDs, minisatellites, chiasma frequency, and organismal traits and also for approximately 200 genes by AFLP (in preparation). Clearly, genomic molecular evolution of nuclear and extranuclear diversities of proteins and DNA, coding and noncoding sequences, in subterranean mole rats, generally assumed to be neutral by proponents of the neutral theory of molecular evolution, is *nonrandom* and correlated positively with increasing aridity stress and climatic unpredictability. The increase in heterozygosity is primarily toward the southern and eastern deserts, where temporal stressful climatic fluctuations and unpredictability climax. Adaptive climatic selection appears to be the prime driving force in both molecular and organismal evolution of mole rats. Natural selection through fluctuating environmental stress (i.e., wider climatic niche) appears to be a major cause of molecular evolution and genome organization in subterranean mole rats, similar to the pattern found in aboveground organisms facing stressful

unpredictable climates, across the same transect of increasing aridity stress (Nevo, 1999).

Local Population Genetics Studies across Sharp Ecological Contrasts

Past Microgeographic Studies in Plants and Animals

Microgeographical studies in nature, particularly those involving sharp contrasts (climatic, thermal, edaphic, geologic, topographic, and chemical), provide remarkable long-term experiments, representing small-scale natural laboratories, for analyzing ecologic genetic population dynamics. Since 1975, we have conducted several microgeographic studies in nature (Nevo, 1998). We employed thermal (high vs low temperature) and chemical (polluted vs clean areas) stresses in marine balanids and conducted an extensive research program on inorganic and organic pollution and its effect on allozyme diversity in marine organisms. Likewise, we examined edaphic (terra rossa vs basalt soil and rock vs deep soil) and microclimatic (sun vs shade and high vs low solar radiation) stresses in wild barley (*Hordeum spontaneum*), wild emmer wheat (*Triticum dicoccoides*), and *Aegilops peregrina*. The conclusions of these studies all point inferentially to natural selection as a major differentiating factor of qualitative and quantitative patterns of genetic diversity at single loci, but primarily at multilocus structures and genome organization (Nevo, 1998, 1999).

The following is the summary of our extensive studies in wild cereals (wild barley and wild emmer wheat) that have been studied spatiotemporally since 1975 at the Institute of Evolution at the protein and DNA levels on micro- and macrogeographical scales. We found significant climatic and soil divergence at four microsites as well as in our macrogeographic studies in Israel and the Near East (Nevo, 1998). All the foregoing studies illustrate massive genetic *nonrandom* divergence at single-locus, two-locus, and multilocus structures of genome organization, with specific and unique alleles and levels of genetic diversity correlated with ecological heterogeneity, niche breadth, stress, and the largely parallel patterns of allozymes, RAPDs, and microsatellites despite increasing differences in levels of genetic diversity in this order (Figure 4). Recently, we have shown the operation of edaphic selection on microsatellites across the microsites of Yehudiyya, Tabigha, and Ammiad (Figure 5). Neither random drift nor gene flow can explain the levels and divergence of genetic diversity at the protein level or at the coding and noncoding DNA regions. The data strongly suggest that natural selection overrides the homogenizing effect of gene flow, maintains molecular polymorphisms in accordance with divergent ecologies, and orients molecular evolution. How general is this genetic divergence pattern of wild cereals, which are predominantly selfers, across life as a whole, primarily in outcrosser plants and nonsedentary animals?

In 1992, we embarked upon a long-term multidisciplinary project at the “Evolution Canyon” microsite. It aims to elucidate the causes of biodiversity and genome evolution at the molecular and organismal levels in diverse groups of organisms across phylogeny from cyanobacteria to mammals, representing a microcosm of life.

Figure 4 Genetic diversity, H_e , of wild emmer wheat, *Triticum dicoccoides*, in four habitats (N, north; V, valley; R, ridge; K, Karst) divided into 11 microhabitats in the Ammiad microsite, Upper Galilee, as reflected in allozymes, microsatellites, and RAPDs (Li *et al.*, 2000a). Note the much higher levels of H_e in microsatellites and RAPDs compared with allozymes; likewise, note the similarity of all systems, but primarily note the high and significant correlation between microsatellites and RAPDs ($r_s = 0.85$, $p = 0.003$; see text). VC, main valley center; VM, main valley margins; VN, narrow valley; N₁, upper north-facing (moderate) slope; N₂, middle north-facing (steep) slope; RE, ridge, east-facing slope; RP₁, ridge, shoulder of plateau; RP₂, ridge, top of plateau; RS, ridge, south-facing slope; K₁, upper karst; K₂, lower karst (reproduced with permission from Li YC, Krugman T, Fahima T, *et al.* (2000a) *Parallel Microgeographic Patterns of Genetic Diversity and Divergences Revealed by Allozyme, RAPD, and Microsatellites in Triticum dicoccoides* at Ammiad, Israel. Netherlands: Springer).

Evolution in Action across Phylogeny caused by Climatic Stresses: “Evolution Canyon”

Biodiversity and genome evolution, and the relative importance of forces driving evolution, are critically tested at the “Evolution Canyon” microsite (Lower Nahal Oren, Mount Carmel), a dynamic ongoing microscale research program (Nevo, 1997). Our aim is to draw generalizations across life in genotypes and phenotypes and to highlight controversial and unresolved problems of biological evolution. The opposed slopes of “Evolution Canyon” display dramatic physical and biotic contrasts on a microscale (Figure 6). Higher solar radiation (up to 600% more) on the south-facing slope (SFS) makes it warmer, drier, and spatiotemporally more heterogeneous and fluctuating than the north-facing slope (NFS). The two slopes are separated by only 100 m (at bottom) and 400 m (at top). The SFS represents an Afroasian savanna park forest, whereas the NFS represents a dense Euroasian live oak maquis forest.

The tropical Afroasian warm and xeric SFS savanna displays wider ecological heterogeneity and higher stress for temperate terrestrial organisms. As predicted, genetic diversity was higher on the ecologically more heterogeneous (wider niche) and stressful SFS in 9 of 11 tested temperate model species (lichen, wild barley, 2 species of land snails, earthworm, diplopod, 3 beetles, and 2 rodents) (Figure 7). In 6 species, heterozygosity

was negatively correlated with population size, i.e., population abundance was lower, whereas genetic diversity was higher on the SFS. This negates the positive correlation expected between H and N_e by neutrality theory (Kimura, 1983). We have shown in wild barley, *H. spontaneum*, that RAPD and sequence-tagged site PCR analysis mirror allozyme interslope patterns.

Remarkably, heritable mutation and recombination rates were several-fold higher in the soil fungus *Sordaria fimicola* and in the fruit fly *D. melanogaster* on the more stressful SFS. Importantly, in terrestrial taxa species richness was higher on the SFS, and interslope adaptive complexes were demonstrated in land snails, *Drosophila*, wild barley, and mice, contributing to differential fitness in morphology, physiology, behavior, and life history. Transplant experiments showed inter- and intraslope-specific fitness components matching the differential ecological stresses (all studies mentioned in this section are cited in Nevo, 1997). Similar results abound in local genetic differentiation in plants (Linhart and Grant, 1996).

We hypothesized that microclimatic diversifying natural selection, overriding migration and stochasticity, appears here as a major evolutionary driving force of genotypic and phenotypic evolution. The “Evolution Canyon” microsite provides a fertile microgeographic critical testing model of biodiversity evolution due to its sharp microscale ecological slope contrasts, both in niche width and in climatic stress.

Figure 5 Discriminant analysis between two soil types, basalt and terra rossa of wild emmer wheat (*Triticum dicoccoides*), across three microsites (Yehudiyya, Tabigha, and Ammiad) north of the Lake of Galilee, Israel. This analysis is based on 2, 5, 10 and microsatellite loci, classifying correctly 21, 83, 88, 90, and 91% of plants into their original soil types (based on data from Li YC, Fahima T, Korol AB, *et al.* (2000b) Microsatellite diversity correlated with ecological-edaphic and genetic factors in three micro-sites of wild emmer wheat in north Israel. *Mol. Biol. Evol.* 15: 5).

Figure 6 “Evolution Canyon,” Lower Nahal Oren, Mount Carmel, Israel Note the plant formation on opposed slopes. The lush, green “European” live oak maquis forest on the temperate, cool-mesic, north-facing slope sharply contrasts with the open park forest of warm-xeric, tropical “Afroasian” savanna on the south-facing slope (SFS). (Top) Cross section; (bottom) air view with the seven experimental stations—three on the SFS (1–3), one at the valley bottom (4), and three on the NFS (5–7) (reproduced from Nevo E (1997) Evolution in action across phylogeny caused by microclimatic stresses at “Evolution Canyon”. *Theor. Population Biol.* 52: 231–243).

The Nature of Allozyme and DNA Diversities

Critical laboratory experiments on marine model organisms have shown that allozymic diversity is adaptive and responds rapidly to environmental inorganic and organic pollution stresses (Nevo, 1998); a large amount of allozymic diversity can be gained or lost rapidly. Our experiments demonstrated unequivocally that ecological stresses of thermal and chemical pollution affect the level and pattern of allozyme allele frequencies and heterozygosity of marine organisms, thereby corroborating the environmental theory of genetic diversity. The survivorship values of heterozygotes and homozygote allozyme genotypes vary in accordance with the pollutant concentration. The broader the ecological niche, the higher the heterozygosity. Furthermore, heterozygote sites mutate more frequently than equivalent homozygous sites, possibly because mismatch repair between homologous chromosomes during meiosis provides extra opportunities to mutate. At medium levels of pollution, heterozygotes seem to be superior, whereas at high pollution levels specific homozygotes become superior.

Our laboratory results on mercury pollution were confirmed in the sea. Remarkably, Schulman and colleagues described dynamic and rapid changes in genome size mediated by an increase or decrease in copy number of the retrotransposon BARE-1 in wild barley, *H. spontaneum*, both regionally and locally in Israel were described in 1999 by Schulman and colleagues.

Evolutionary Significance of Molecular Polymorphisms: Summary and Evidence

The foregoing macro- and microscale field and laboratory evidence across phylogeny displays massive genetic parallels to environmental heterogeneity and diverse stresses, physical (thermal, climatic, and edaphic) and biotic (pathogens, competitors, vegetation, and habitats). In general, higher levels of genetic polymorphisms, at both the protein and the DNA levels, occur under more stressful and variable environments. This is highlighted by the enormous diversity recorded in the vertebrate major histocompatibility complex (Bodmer

Figure 7 Genetic (allozyme) diversity in major plant and animal taxa on the opposed slopes of “Evolution Canyon”—the mesic, temperate, and mild north-facing slope (NFS) and the xeric, tropical, and stressful south-facing slope (SFS). *Caloplaca aurantia* (lichen), *Hordeum spontaneum* (wild barley), *Bimastos syriacus* (earthworm), *Buliminus labrosus*, *Pomatias olivieri*, and *Levantina caesareana* (land snails), *Tetrarthrosoma syriaca* (diplopod), *Carabus hemprichi* and *Oxythyrea noemi* (beetles), and *Acomys cahirinus* and *Apodemus mystacinus* (rodents) are presented. The genetic diversities represent allozyme heterozygosity observed (H) or expected (H_e). *Comparison between the highest stations (H_e); #, *Tetrarthrosoma syriacum* (reproduced from Nevo E (1997) Evolution in action across phylogeny caused by microclimatic stresses at “Evolution Canyon”. *Theor. Population Biol.* 52: 231–243).

and Bodmer as cited in Wasser, 1999) and immunoglobulin gene families, resistance genes in plants, against the immense pathogen diversity, and in the regulation of clock genes. Linkage disequilibria and genome organization (Nevo, 1998) are correlated with higher environmental heterogeneity (also called the niche width variation hypothesis by Van Valen, which predicts positive correlation between niche width and morphologic variation) and stress (Figures 3 and 7). Similarly, mutation and recombination rates in the soil fungus *Sordaria fimicola* and in male *Drosophila melanogaster* at “Evolution Canyon” were both higher on the ecologically more heterogeneous and stressful SFS. Ecological heterogeneity and stress appear to be major determinants of the level of genetic diversity in nature, as was demonstrated in numerous organisms (Mitton, 1997). Physical and biotic ecological variables are better predictors of genetic diversity than demographic variables of population and species size. In fact, the levels of genetic diversity are often negatively correlated with effective

population size, negating neutrality theory predictions. Generally, genetic polymorphism is positively correlated with niche width, or the level of ecological heterogeneity and stress, as emerged from our global, regional, and local analyses and from critical laboratory experiments. A brief theoretical discussion follows.

Theory

Mechanisms of Generating Genetic Diversity

It is beyond the scope of this article to describe the mutation mechanisms that generate diversity. Suffice it to say that a host of mechanisms provide a permanent input of diversity into natural populations, including point mutations, deletions, additions, recombination, gene conversion, and mismatch repair. Mutation rates also vary dramatically among organisms and genes and under diverse ecological stresses. Evidence from bacterial genetics (Casjens, 1998) suggests that organisms can resist stress through mutational changes or acquisition of pre-evolved functions via horizontal transfer. Activating mutagenic response and inhibiting antimutagenic activities (e.g., mismatch repair) could be important in recruiting genetic diversity as an adaptation to stress. Stress-induced increases in mutation rates enhance genetic polymorphism, primarily in genomic “hot spots.”

Significance of Genetic Diversity

The functional value of genetic diversity within populations has been confirmed in a series of studies. Clearly, this rich pool of diversity provides the resource for continuous selection of adapted genotypes. Reduced genetic diversity may not only compromise the capacity of an impacted population for genetic adaptation in the face of further environmental challenge but also may result in increased energy requirements, lower production efficiency, and reduced homeostasis and reproductive output. These metabolic consequences of reduced genetic polymorphism would further lower that population’s potential for survival under lethal conditions of contaminant exposure and also affect the genetic makeup of populations through differential reproduction under conditions of sublethal stress. In laboratory studies with population cages, higher levels of allozyme and additive genetic diversity are generally maintained in cages with greater heterogeneity, as is also generally true in nature (Mitton, 1997). Genetic diversity makes it possible to establish genetic distances within and between species, identify species and strains by unique and specific genetic profiles, establish phylogenetic trees, reinforce conservation biology and management programs, and have profound implications for plant and animal husbandry in agriculture and medicine.

Maintenance of Genetic Diversity in Nature

Explaining the maintenance of genetic diversity in natural populations has been a central problem of evolutionary genetics since the discovery of abundant protein polymorphisms in nature (Lewontin, 1974; Nevo, 1978, 1988, 1998; Kimura, 1983; Gillespie, 1991; Avise, 1994; Mitton, 1997). It is now

clear that stochastic and bottleneck explanations, relating heterozygosity primarily to population size effects, are not realistic. Populations are rarely at equilibrium because environmental conditions fluctuate with abiotic (e.g., climate and seasons) and a host of biotic (e.g., parasites, pathogens, and competitors) factors. Correspondingly, genetic diversity can be gained or lost rapidly in dynamically changing natural populations due to ecological stresses. The major models explaining genetic diversity in nature relate primarily to the levels of ecological heterogeneity (niche breadth) and stress, or multinationes, and to environmental grain (Levins, 1968) rather than to effective population size or gene flow. Environmental variability enhances genetic diversity. Natural selection appears to be a major driving evolutionary force maintaining genetic diversity in nature (Bell, 1997). However, heterosis (i.e., overdominance or heterozygote advantage) alone is not a mechanism for maintaining many alleles segregating at a locus, as argued in 1978 by Lewontin, Ginzburg, and Tuliapurkar; hence the resort to spatiotemporal driving forces at multilocus structures.

Natural Selection

Theoretically, spatial and temporal variations of selection ("diversifying selection") could maintain and enhance genetic polymorphisms, although the conditions of their applicability are strongly limited (see cited papers by Levene, Haldane, Karlin, Lande, Felsenstein, Hedrick, Hoekstra, Maynard Smith in Ewens (1979) and Nevo (1998)). Spatial variation appeared more effective than temporal variation, although their joint action could reinforce the maintenance of polymorphism. Most results related to selection of variation in time were derived from the one-locus case. Polymorphism maintenance may be reinforced in the case of two-locus or multilocus structures (Gillespie, 1991; Kirzhner *et al.*, 1998). Fitness components (viability, growth rate, fecundity, mating success, and developmental stability) increase with heterozygosity, suggesting that selection balances diversity at protein polymorphisms (Mitton, 1997). Some of the correlations between heterozygosity and fitness components can be attributed to allozyme loci or loci in strong linkage disequilibrium with them. This positive relationship between heterozygosity and fitness is not only expected theoretically but also abundantly documented empirically (Mitton, 1997). The selective mechanism is much more effective in promoting genetic diversity if carriers of the alternative alleles are able to select the niche in which their fitness is greatest as argued in 1977 by Taylor and Powell and by Nevo and colleagues in 2000 for mole crickets. For selection theories of molecular evolution and polymorphism based on the combined forces of natural selection, genetic drift, and mutation, see Gillespie (1991). For a discussion on the development of neutral and nearly neutral theories, see Ohta and Gillespie (1996). A series of articles dealing with natural selection and Darwinian fitness in nature appear in Wasser (1999).

In a series of articles and books during the period 1931–1978, Sewall Wright developed his "adaptive landscape" theory. In this model, populations are imagined to spend most of their time on selective peaks, with genetic drift providing the push when a population jumps from one peak to another. In contrast, Fisher's (1958) model on the nature of adaptation

assumes that a population is never exactly at its optimal phenotype. Likewise, in Gillespie's (1991, pp. 291–305) random environment selection theories, there are no analogs to adaptive peaks because the adaptive landscape is changing faster than the genetic system: "The population is always running uphill, but the peak is always two steps ahead. All the population ever sees, in effect, is the side of the mountain. Should it stop evolving, it will face extinction." This view is related to Fisher's model and to the red queen hypothesis of Van Valen (1973), which assumes that if a population does not continue to adapt at the same rate as its competitors or environmental deterioration it may become extinct.

Stabilizing Selection in Cyclical Environments

Stabilizing selection for an intermediate optimum is generally considered to rapidly deplete genetic diversity in quantitative traits, with increased number of loci. In contrast to previous conclusions, we found in both haploids and diploids, in the case of an additive two-locus model, that stabilizing selection with cyclically moving optimum may be an efficient factor in protecting polymorphisms for linked loci additively affecting the selected trait (Korol *et al.*, 1994; Kirzhner *et al.*, 1998). We proved that within the same class of fitness functions, nonequal gene action and/or dominance effect for one or both loci may lead to local polymorphism stability with substantial polymorphism-attracting domain. A higher intensity of selection could result in two forms of polymorphic limiting behavior: (i) the usually expected forced cycles with a period equal to that of environmental changes and (ii) "supercycles," which are nondamping autooscillations with a period composed of hundreds of forced oscillations.

We have demonstrated (Kirzhner *et al.*, 1998) that a multilocus system subjected to stabilizing selection with cyclically moving optimum can generate ubiquitous complex limiting behavior, including supercycles, T cycles, and chaotic-like phenomena. This mode of multilocus dynamics far exceeds the potential of complex dynamics attainable under ordinary selection models resulting in simple behavior. It may represent a novel evolutionary mechanism increasing genetic polymorphism over long-term periods (Kirzhner *et al.*, 1998).

Selection versus Genetic Drift in Small Isolated Populations

Remarkably, our findings of high-level heterozygosity in small (several dozen or 100 individuals) desert isolates of the subterranean mole rats, *Spalax ehrenbergi* superspecies ($2n = 60$), in the northern Negev (Nevo, 1999) contradict both the Wrightian notion of genetic drift in small populations that was elaborated in 1931 and the extreme version of genetic drift, i.e., the neutral theory of molecular evolution (Kimura, 1983). The latter predicts positive correlation between effective population size (N_e) and heterozygosity H , whereas our finding demonstrated the opposite (i.e., the highest level of H in the smallest populations, or a negative correlation between H and N_e). A negative correlation between population size and heterozygosity was also found in several species tested at the "Evolution Canyon" micro-site (Nevo, 1997). Current theoretical models predict fast gene fixation in small panmictic populations without selection, mutation, or gene inflow. Using simple multilocus models, we demonstrated that

moderate stabilizing selection (with stable or fluctuating optimum) for traits controlled by additive genes could oppose random fixation in such isolates during thousands of generations (Nevo *et al.*, 1997a, as cited in Nevo, 1999). We also showed that in selection-free models polymorphism persists only for a few hundred generations even under high mutation rates. Our multichromosome models challenge the hitchhiking hypothesis of polymorphism maintenance for many neutral loci due to close linkage with a few selected loci.

Genetic Ecological Diversity and Stress

The foregoing discussion suggests several explanations for the maintenance of genetic diversity subjected to ecological diversity and environmental stress. Spatial and temporal ecological variation, which predominates in nature, is of prime importance in maintaining and enhancing genetic diversity in natural populations. This may be true because different genotypes display varying fitnesses in variable environments and stresses. Recombination frequencies and mutation rates tend to increase under stressful conditions (Hoffmann and Parsons, 1991; Korol *et al.*, 1994; Nevo, 1997). Rates of evolutionary change are therefore enhanced in adverse environments, as was demonstrated under controlled laboratory experiments in the case of mercury pollution (Baker *et al.* as cited in Nevo, 1998), under regional aridity stress across the physically stressful Israeli environment, and locally at "Evolution Canyon" because of high solar radiation on the SFS (Nevo, 1997).

Developmental instability may be enhanced under both environmental stress and genomic stress. This could increase genetic diversity under stressful conditions (Hoffmann and Parsons, 1991). Heterozygote advantage tends to increase diversity with stress up to extreme points. However, heterosis alone is not a mechanism for maintaining many alleles segregating at a locus. It is much more likely that stable equilibria for multiple alleles will be best explained by multiple-niche selection. Models of sexual reproduction as an adaptation to resist parasites proposed by Hamilton and colleagues in 1990 may also contribute to sex evolution, recombination, and polymorphism. Finally, the simple model advanced by Kirzhner and colleagues in 1999 of genetic interaction between multiple species on a trait for trait basis governed by abiotic and biotic selection for multilocus quantitative traits opens wide horizons for the evolution of genetic diversity due to species dynamic interactions in nature.

Ecological heterogeneity and stress appear to enhance genetic polymorphisms, particularly in dynamically cycling environments (which can generate complex dynamic-like supercycles and chaotic-like behavior). This mode of multilocus dynamics far exceeds the potential for maintaining genetic polymorphism attainable in ordinary selection models. It may represent a novel evolutionary mechanism increasing genetic polymorphism over long-term periods. This novel mechanism could contribute to the observation that biological diversity has increased over geological time despite the well-known massive extinctions, providing ever-increasing genetic diversity and thus enhancing the evolution of biodiversity.

Glossary

Allele One of two or more different forms of a gene.

Coadapted gene complexes Chromosomes, loci, or genes that are adapted to function well together.

Effective population size (N_e) Size of the ideal population used in population genetics theory that would have the same rate of increase in inbreeding or decrease in genetic diversity as the actual population under study.

Genetic drift Changes in the frequency of alleles within a population over time due to the random process of passing alleles from parents to offspring.

Lethal equivalent Group of mutant alleles that would cause an average of one death if homozygous; for example, one lethal equivalent might represent two mutant alleles, each with a 50% probability of causing death, or any other combination of mutant alleles that would produce an average of one death.

Outcrossing A mating system in which individuals breed with other individuals that are not related to them.

Selection differential(s) A measure of the intensity of selection on a phenotypic character.

Inbreeding

Inbreeding is the production of offspring from the mating of individuals related by ancestry. This includes self-fertilization, brother–sister, parent–offspring, and cousin matings, as well as matings between more distant relatives. Inbred offspring are more likely to inherit recent copies of the same allele from both parents, that is, alleles that are identical by descent (derived from a common ancestor of both the parents). Two alleles that are identical by descent are homozygous, but not all homozygous alleles are identical by descent. A homozygous individual has two alleles at a locus that are functionally similar. However, these two alleles may or may not be identical by descent.

The inbreeding coefficient (usually symbolized by F) of an individual is the probability that the individual has two alleles at a locus that are identical by descent. Because F is a probability, it ranges from 0 for noninbred individuals to 1 for completely inbred individuals. For example, the inbreeding coefficient of an individual resulting from self-fertilization is $1/2$ and that for an individual resulting from a parent–offspring or brother–sister mating is $1/4$.

Because the process of inbreeding increases the likelihood that two alleles in a genotype are identical by descent, inbreeding increases the frequency of homozygotes, and reduces the frequency of heterozygotes in direct proportion to the inbreeding coefficient. A population with an average inbreeding coefficient of 10% will have 10% less heterozygosity than a similar noninbred population.

Inbreeding Depression

Natural populations contain low frequencies of deleterious recessive mutations (due to the balance between their occurrence by mutation and removal by selection) that are normally found as heterozygotes and are thus not expressed. Inbreeding

increases the probability of individuals inheriting these recessive alleles as homozygotes, thus enabling the expression of their deleterious effects. Consequently, in most populations of animals and plants, inbreeding results in a decline in reproduction and survival (reproductive fitness), which is called inbreeding depression.

Another cause of inbreeding depression is overdominance. Different genotypes have different effects on fitness. In some traits or loci, even though alleles are not recessive, the homozygous genotypes (e.g., AA and aa) are, on average, less fit than the heterozygous genotype (Aa). These traits or loci are referred to as overdominant or showing heterozygote advantage. As inbreeding decreases the proportion of the fitter heterozygotes in a population, the average fitness (e.g., reproduction and survival) of the population declines, resulting in inbreeding depression.

Studies show that most inbreeding depression is due to the accumulation of deleterious recessive mutations, rather than overdominance.

Evidence for Inbreeding Depression

The deleterious effects of inbreeding were known long before the discovery of the underlying Mendelian mechanisms that cause it. In the nineteenth century, Charles Darwin clearly documented inbreeding depression based on studies in 57 species of plants, as well as the experience of livestock breeders. These early observations were amply confirmed by subsequent studies. There is now extensive evidence for inbreeding depression in laboratory and domestic animals and plants, as well as considerable evidence for inbreeding depression in wild animals and plants. Many studies on inbreeding were massive, involving large numbers of animals over many years, and the literature is extensive. For example, Sewall Wright's classic experiments on inbreeding in guinea pigs resulted in the production of 29,310 inbred and 5105 control young from 1906 to 1924. Only the five most vigorous inbred lines survived to the

end of the experiments; 30 other inbred lines went extinct or declined so severely that Wright discontinued breeding them before the end of the experiment. Nevertheless, the surviving inbred guinea pigs were consistently inferior to the controls in number of young born, percentage of young born alive and raised to 33 days, and weight at 33 days.

Inbreeding and selection have been used to fix desirable traits in modern breeds of livestock. However, reduced fertility was a major problem during the early periods of inbreeding and the inbred lines were repeatedly outcrossed to restore vigor and fertility. The North Central regional dairy cattle-breeding project (involving Iowa, Michigan, Minnesota, Missouri, Ohio, South Dakota, and Wisconsin), begun in 1947, is an example of the many extensive studies on inbreeding in livestock. This study found that inbreeding usually increased juvenile mortality and decreased milk yield, fat yield, growth, and reproductive performance.

Inbreeding depression is also well known in zoo animals. For example, in the early 1980s, scientists at the National Zoo found that juvenile mortality was higher in inbred than in noninbred offspring in 41 of 44 populations of mammals in zoos, including many primates, antelopes, and deer, as well as a variety of smaller mammal species (Figure 1). On average, the progeny of father–daughter and brother–sister matings suffered a 33% reduction in juvenile survival compared with outbred offspring. However, the severity of inbreeding depression varied widely across species. Although inbreeding in zoo animals usually results in less vigorous and fertile

individuals that appear phenotypically normal, it is also responsible for some genetic diseases in captive populations, including blindness in wolves and dwarfism in California condors. Zoo populations are now routinely managed to avoid inbreeding.

Evidence for inbreeding depression in natural environments has been reported in many species (Keller and Waller, 2002). A review of the literature on inbreeding effects in wild vertebrates and plants found that 90% of 157 data sets showed inbreeding depression, indicating that species frequently exhibit moderate to high levels of inbreeding depression under natural conditions (Crnokrak and Roff, 1999). Species showing inbreeding depression include mammals (golden lion tamarins, lions, native mice, shrews, and Soay sheep), birds (greater prairie chicken, Mexican jay, song sparrow, American kestrel, and reed warbler), fish (Atlantic salmon, desert topminnow, and rainbow trout), a reptile, a snail, an insect (butterfly), and many species of plants. Some studies have failed to find inbreeding depression, but these have typically been small studies or ones where paternity has not been verified. For example, no inbreeding depression was found in superb fairy wrens in Western Australia, but subsequent paternity studies using molecular genetic methods revealed that 64% of progeny were not fathered by the males to whom paternity had previously been attributed. Because inbreeding depression is so common, management of an unstudied outbreeding species should be based on the assumption that it will suffer reductions in reproductive fitness if it is inbred.

Figure 1 Juvenile mortality in inbred and noninbred young in 45 populations of mammals in captivity. Inbreeding levels were calculated with respect to the founders of the population for which the pedigree data were available. Most populations were founded with wild-caught animals but some were founded with animals from other zoos or of unknown origin. The noninbred category includes all animals with an inbreeding coefficient of 0 and the inbred category included all of those with an inbreeding coefficient greater than 0. For the larger species, all young surviving up to 6 months or more were considered to have survived. For the small species, one-half of the age at sexual maturity was used as the criterion age. Numbers above the bars indicate sample sizes for each species. Reproduced from Ralls K and Ballou J (1986) Captive breeding programs for populations with a small number of founders. *Trends in Ecology and Evolution* 1: 19–22.

Figure 2 Decreasing juvenile survival with increasing inbreeding in golden lion tamarins (*Leontopithecus rosalia*). The proportion of offspring with a given inbreeding coefficient surviving to 7 days of age is plotted against the inbreeding coefficient. The sizes of the ovals represent the number of offspring available to estimate survival for each level of inbreeding. Large ovals represent samples of more than 50 offspring, medium ovals from 30 to 50, small ovals from 10 to 30, and tiny ovals from 1 to 10.

Factors Affecting the Severity of Inbreeding Depression

The degree of inbreeding depression in a population depends on the extent of inbreeding, the original frequency of deleterious recessives, the environment, and chance. Continued inbreeding results in greater inbreeding depression. For example, average levels of various components of reproductive fitness, such as juvenile survival in mammals (Figure 2) or grain yield in maize, theoretically decrease in a linear fashion as the inbreeding coefficient increases. The more deleterious alleles that were formerly masked by heterozygosity, the more severe the effects of inbreeding will be.

Severity of inbreeding depression also depends on the environmental conditions. Under benign conditions, many inbred plants and animals may survive. However, inbreeding depression is greater under more stressful conditions. Selfed progeny of one species of plant showed 75% inbreeding depression in the field but only 59% in garden plots and 53% in a greenhouse (Dudash and Fenster, 2000). A meta-analysis of 34 studies concluded that inbreeding depression was, on average, 69% more severe in stressful than in benign environments (Crnokrak and Roff, 1999).

Measuring Inbreeding Depression as Lethal Equivalents

The extent of inbreeding depression in survival of animals can be measured in terms of lethal equivalents. The number of lethal equivalents per gamete or individual can be calculated from the rate that survival decreases with increasing inbreeding. A study of 40 captive populations of mammals found an average of 4.6 lethal equivalents per individual for juvenile survival (Ralls *et al.*, 1988). Thus, each individual contained enough deleterious mutations to have an effect equivalent to slightly <5 single lethal mutations if they were homozygous. This figure is similar to estimates done in humans and birds.

However, the number of lethal equivalents varied widely across captive populations. Estimates of lethal equivalents based on survival to progressively older ages tend to increase. For example, wild song sparrows had 2.9 lethal equivalents based on survival from egg to independence but 5.4 lethal equivalents based on survival from egg to age at first breeding (Keller, 1998).

Inbreeding Depression in Total Reproductive Fitness

Most studies of inbreeding depression measure only one or a few components of reproductive fitness. However, since all traits have the potential to accumulate deleterious recessive alleles as a result of mutations, it is expected that all components of reproductive fitness will be subject to inbreeding depression. In animals, this includes offspring survival, number of offspring per female, male mating ability, sperm quality, disease resistance, and the quality and quantity of maternal care. Greater inbreeding depression for overall fitness than for its components has been found for old field mice, house mice, chickens, turkeys, Japanese quail, chukar partridges, and song sparrows. A meta-analysis estimated that wild populations have an average of about 12 lethal equivalents across the lifecycle (O'Grady *et al.*, 2006). In song sparrows, eggs with an average inbreeding coefficient of 0.25 have a 79% loss of fitness distributed over various life history stages: egg survival to breeding age was reduced by 49%, adult survival by 24%, and lifetime reproductive success of females by 48%. In the Takahe, an endangered New Zealand rail, inbreeding led to only small reductions in fitness at individual life history stages, the deleterious effects were cumulative across multiple life history stages and significantly reduced long-term fitness. Successful recruitment of second-generation offspring was reduced by 88% in full sib pairs compared to unrelated pairs.

Susceptibility to Inbreeding Depression

Inbreeding depression has a large chance (stochastic) element because of the random sampling of alleles during reproduction. Individuals with the same inbreeding coefficient, that is, the same probability of carrying alleles identical by descent, will differ in actual levels of homozygosity for any given trait, and, thus, will vary in the degree to which they experience inbreeding depression. Families and populations within a species carry different types and numbers of deleterious mutations and differ in their susceptibility to inbreeding depression. Differences in the extent of inbreeding depression among lineages within species are common, including mice, dairy cattle, fruit flies, and flour beetles and are to be expected in all outbreeding species. These differences contribute to the occasional success in establishing inbred lines or wild populations from the progeny of a small number of founding individuals even in species that typically show high levels of inbreeding depression. Differences among populations within species have also been reported. No differences in susceptibility to inbreeding depression among major taxonomic groups are known, but the relevant data are limited.

Figure 3 Relationship between inbreeding depression and the selfing rate in several species of herbaceous angiosperms. Species are G, *Gila achilleifolia*; Ch, *Chamaecrista fasciculata*; S, *Sabatia angularis*; Cu, *Cucurbita foetidissima*; C, *Clarkia tembloriensis*; and E, *Eichhornia paniculata*. For *Clarkia* and *Eichhornia*, data from three populations are plotted. Inbreeding depression for these species was measured in the lath house and glasshouse, respectively; all others were measured in the field. Reproduced with permission from original Figure 1.7 in Falk DA and Holsinger KE (1991) *Genetics and Conservation of Rare Plants*, 23 pp. New York: Oxford University Press, Inc.

Species that naturally inbreed (e.g., selfing plants and mole rats) occasionally show lower levels of inbreeding depression than naturally outbreeding species (Figure 3). Slow rates of inbreeding over long periods of time have the potential to select against and remove deleterious alleles (i.e., purge, see below) in these inbreeding populations, reducing their inbreeding depression. While these types of species often show less inbreeding depression, they still do exhibit detectable levels of inbreeding depression when inbred further.

Efforts to predict the susceptibility of specific populations or species to inbreeding depression have not been successful owing to the extremely stochastic nature of inbreeding depression.

Inbreeding and Outbreeding in the Wild

Only about 20% of species regularly self-fertilize and these tend to have life histories that strongly favor mating with relatives. For example, many are colonizing species in which the chances of successfully dispersing are much higher if only a single individual has to reach a new habitat. The restricted taxonomic distribution of selfing to some plants, terrestrial slugs, and marine invertebrates suggests that it is an evolutionary dead end.

The majority of species appear to be naturally outbreeding. Many plants that are pollinated by insects have elaborate morphological mechanisms that favor cross-pollination. In other plants, cross-pollination is ensured because the male and female gametes do not mature at the same time. Another mechanism that prevents self-fertilization is self-sterility, in which the pollen either fails to germinate on a stigma of its own flower or germinates, but does not develop sufficiently to fertilize the egg.

Many animals are also thought to avoid close inbreeding. Although a few mammals, notably the naked mole rat, normally mate with close relatives and are highly inbred, most mammals and birds rarely mate with close relatives. Sex differences in dispersal patterns often limit opportunities for inbreeding. In most mammals, males tend to disperse more frequently or farther than females, whereas the reverse is true in birds. Furthermore, many species can recognize close kin, and a variety of species such as jays, woodpeckers, mice, voles, ground squirrels, black-tailed prairie dogs, and chimpanzees are known to actively avoid mating with them.

Inbreeding Depression in Small Populations

Inbreeding is unavoidable in small, closed populations because all individuals eventually become related to each other. Inbreeding in a population of size N_e increases at a rate of $1/(2N_e)$, per generation with random mating. For example, in an effective population of size 10, there is a 5% increase in inbreeding per generation. Consequently, small, isolated populations that have existed for many generations are expected to show inbreeding depression. Small populations of plants, fruit flies, a rock wallaby, Florida panthers, and a snake have been found to suffer from inbreeding depression. However, inbreeding depression may not cause declines in population size. Reduced fecundity and survival will only cause a population to decline to extinction if the reproductive rate drops below the replacement level. Small (and large) populations can also suffer from reduced reproductive fitness because of declines in environmental quality.

Reduction of Inbreeding Depression

Inbreeding depression may be reduced by selection against deleterious alleles, which eliminates, or purges, them from the population. Purging has been documented in plants, mice, birds, and fruit flies, and during the development of inbred lines in a variety of species. Species that naturally inbreed should theoretically show less inbreeding depression than naturally outbreeding species because of the greater opportunity for selection against deleterious recessives.

Purging can reduce inbreeding depression, but it is unlikely to eliminate it. In captive mammals, selection led to a small reduction of inbreeding depression in neonatal survival in 15 of 17 populations. No trends in purging effects were observed in survival to weaning or litter size. The purging effects were not strong enough to be of practical use in captive breeding programs. Lacy and colleagues found that the effectiveness of natural selection in reducing inbreeding depression varied substantially in experiments with three subspecies of captive deer mice, probably due to different histories of inbreeding and selection in the wild prior to capture. Reviews on the effects of purging have pointed to a variety of effects from nil to moderate. In sum, it remains impossible to make strong predictions about the situations under which purging will occur and the probable magnitude of purging effects in individual populations. Therefore, genetic management programs for captive populations currently aim to minimize inbreeding

rather than undertake deliberate inbreeding in an attempt to purge deleterious alleles from populations.

Inbreeding depression can be completely reversed by outcrossing an inbred population to another unrelated population, either an outbred population or an independently inbred population. Crossing two highly inbred, but unrelated, populations results in an outbred population with a high level of heterozygosity and little inbreeding depression, since the high heterozygosity effectively masks the deleterious alleles that were being expressed in the inbred populations. This effect is termed "hybrid vigor." Partial recovery can be achieved by introducing unrelated individuals into an inbred population. Several wild populations showing signs of severe inbreeding depression have benefited dramatically from the introduction of unrelated individuals. Examples of such genetically stimulated recovery are known from a broad range of taxa including mammals (deer mice, gray wolves, Florida panthers), birds (prairie chickens), reptiles (adders), fish, and plants.

Inbreeding, Loss of Genetic Diversity, and Extinction

Many conservation biologists have been concerned that inbreeding and loss of genetic diversity in small populations will increase the risk of extinction. However, some researchers have questioned this view because of the difficulty of obtaining direct evidence that inbreeding contributes to the extinction of wild populations.

Inbreeding and Extinction in Captivity

There is overwhelming evidence that deliberately inbred populations of laboratory and domestic animals and plants suffer elevated extinction rates, as illustrated in Figure 4. Extinctions were rare at low levels of inbreeding but sharply increased when inbreeding reached intermediate levels as it generally takes several generations and considerable inbreeding until the growth rate of the population becomes negative.

Figure 4 Relationships between survival of populations and inbreeding (F) for *Drosophila melanogaster*, *Drosophila virilis*, and house mice. All populations were inbred using full-sibling mating, except for the use of cousin mating in the first generation in *Mus musculus*. Reproduced from Frankham R (1995) Inbreeding extinction: A threshold effect. *Conservation Biology* 9: 792–799, with permission from Wiley.

Most attempts to develop inbred lines by intense inbreeding are unsuccessful. Of the 20 colonies of laboratory mice maintained by sibling mating in Figure 4, 19 became extinct by generation 12, but the remaining colony showed no decline in litter size and became a successful inbred line. Results with fruit flies, guinea pigs, poultry, and Japanese quail are similar.

Slower rates of inbreeding also lead to extinctions. Small populations of fruit flies maintained at effective sizes of 10 and 20 had greatly elevated extinction risks, even though these were slightly lower than those of populations subjected to intense inbreeding (full-sibling mating) when all were compared at the same inbreeding levels. Further, all the larger populations that survived to high levels of inbreeding had fitness levels lower than those of outbred controls, leading these authors to conclude that although slower rates of inbreeding may slightly slow extinction rates, they do not offer a solution to the increased extinction risk associated with inbreeding in small populations. The effects of inbreeding on population viability are complex and will interact with other factors affecting population growth, population fluctuations, or N_e , but they will be deleterious in the long term (Figure 4).

Inbreeding and Extinction Risk in Wild Populations

Conservation biologists initially thought that genetic problems played a role in the endangerment and extinction of wild populations. It was clear that inbreeding increased extinction risk in laboratory populations and theoretical work in the 1980s suggested that small populations in the wild should also suffer from increased extinction due to the unavoidable increase in mating between close relatives. However, in an influential paper, Lande argued that random demographic and environmental events drive small wild populations to extinction before genetic factors cause problems. Environmental events, ranging from annual variation in climatic variables (such as rainfall) to catastrophes (such as fires and disease epidemics), do increase the probability of extinction and it is extremely difficult to isolate genetic effects from these other effects because inbreeding typically interacts with demography by reducing fecundity, juvenile survival, and life span. Consequently, other researchers continued to question the significance of genetic factors because of the lack of direct evidence that inbreeding can contribute to the extinction of wild populations. However, more recent work has supported the original view that genetic factors can contribute to the extinction of wild populations.

The hypothesis that nongenetic factors would usually drive species to extinction before genetic factors could impact them was evaluated by comparing heterozygosity levels in threatened taxa with those of taxonomically related nonthreatened taxa (Spielman *et al.*, 2004). In 77% of 170 comparisons, heterozygosity levels were lower in the threatened taxa, which would not be expected under the hypothesis that extinction generally occurs prior to genetic impacts. Thus, the view that extinction would occur prior to genetic impacts was rejected. Direct evidence for an impact of inbreeding on extinction risk was provided by studies on the Glanville fritillary butterfly in Finland (Saccheri *et al.*, 1998). They studied a metapopulation (a population of populations) of this butterfly that consists of

numerous small populations that breed in about 1600 dry meadows of different sizes at varying distances from each other. Caterpillars feed in conspicuous family groups of 50–250 individuals and the smallest populations consist of the offspring of a single pair. Populations in individual meadows often go extinct, but many meadows are eventually recolonized, with an average of 200 extinctions and 114 colonizations per year.

Because small population size results in both inbreeding and loss of genetic variation, the researchers were able to use the degree of genetic variation in each population as a measure of the extent to which it was inbred. They sampled 42 populations and found that populations with less genetic variation were more likely to go extinct. Furthermore, genetic diversity predicted extinction risk after they had accounted for all other known causes of extinction in this well-studied butterfly metapopulation. Inbreeding reduced egg-hatching rate and larval survival, lengthened the duration of the pupal period (so that inbred pupae were more likely to be parasitized), and shortened female life span (so that inbred females tended to lay fewer eggs).

Extensive replicated experiments with the annual plant, *Clarkia pulchella*, also found that decreased genetic effective population size (resulting in both inbreeding and loss of alleles through genetic drift) increased the probability of population extinction substantially above that expected from demographic and environmental stochasticity alone. A Spanish study of the shore campion plant reached similar conclusion.

More indirect evidence that inbreeding depression increases the extinction risk of threatened taxa has been provided by stochastic computer simulation models that include inbreeding effects. For example, O'Grady *et al.* (2006) found that incorporating realistic levels of inbreeding depression in population viability models decreased median times to extinction for 30 species by an average of 37%.

Outbreeding and Outbreeding Depression

Mating between distantly related individuals, such as individuals from different populations or subspecies, is called outbreeding. Crossing populations may increase reproductive fitness by increasing heterozygosity and thus preventing the expression of deleterious recessive alleles ("hybrid vigor") or may decrease fitness because of various kinds of genetic incompatibilities between the genes from the different populations (outbreeding depression). Outbreeding depression is a reduction in reproductive fitness, reduced ability to mate or pollinate, fertilize, produce offspring, survive, or reproduce, in the first or later generations following the crossing of populations.

Causes of Outbreeding Depression

Three main mechanisms have been proposed as causes of outbreeding depression: chromosomal incompatibilities, adaptive differentiation among populations, and genetic drift. It is well known that fixed chromosomal differences between two populations increase the probability of outbreeding

depression if the populations are crossed and many cases have been documented in both animals and plants. Although the risk of outbreeding depression differs according to the type of chromosomal differences between populations, it generally increases as the number of fixed differences increases. The risk is greatest with polyploidy, followed by translocations, centric fusions, and inversions.

There is also theoretical and empirical evidence for outbreeding depression between populations that have adapted to different environments. Natural selection can promote rapid development of reproductive isolation, which results in outbreeding depression, between populations in differing environments. A positive association between ecological divergence in reproductive isolation was found in over 500 species pairs of vertebrates, invertebrates, and plants. Most genes involved in prezygotic reproductive isolation that have been investigated show molecular signals of positive selection. Whether or not all cases of reproductive isolation not due to chromosomal incompatibilities are due to adaptation to differing environments remains controversial but adaptation is clearly involved in many cases.

The ecological mechanism of outbreeding depression requires that populations develop different adaptations in response to different local environments. Crossing individuals from the populations may then produce progeny that are less well suited to either local environment. This kind of outbreeding depression is usually observed in the F1 generation. Populations isolated in different environments may also develop coadapted gene complexes, which are sets of genes that have evolved together to produce a fitter phenotype. Crossing individuals from populations with different coadapted gene complexes could then disrupt these complexes and reduce reproductive fitness in the F2 and subsequent generations, when recombination during meiosis disrupts gene complexes.

Genetic drift in small populations has been proposed as a mechanism leading to reproductive isolation (and hence outbreeding depression). Genetic drift can result in chromosomal differences between populations and this often results in outbreeding depression. However, when the chromosomes in two populations are the same, selection is much more likely to result in reproductive isolation than genetic drift. Both theory and extensive empirical evidence indicate that reproductive isolation results predominantly from selection, rather than drift. For example, phenotypic differences due to natural selection were a better predictor of reproductive isolation than genetic distance due to drift in several groups of organisms, including poison-dart frogs, anole lizards, and cichlid fish.

Evidence for Outbreeding Depression

Evidence for outbreeding depression comes primarily from organisms with extremely limited dispersal, such as some plants, copepods, and scale insects, or from crosses between individuals from vastly different geographic sources, or with significant chromosomal differences. Outbreeding depression appears to be more common in plants than in animals. A recent review listed 35 cases of outbreeding depression in vertebrates, invertebrates, and plants. There is not much evidence for outbreeding depression in larger animals, although

it has been observed in crosses where there are chromosomal differences between populations such as in dik-diks and spider monkeys. Such cases usually indicate the existence of unrecognized species or subspecies. The Arabian oryx suffers simultaneously from inbreeding and outbreeding depression. Outbreeding depression appears to be the larger effect but there are chromosomal differences segregating in the population. The most widely quoted mammalian case concerns two ibex populations in Slovakia that lived in very different environments. Several studies have failed to find outbreeding depression in mammals, including in rhesus macaques and saddle-back tamarins. Studies also found no outbreeding depression in survival in several captive populations, including crosses between Borneo and Sumatran orangutans. Lacy and colleagues conducted numerous crosses among five subspecies of deer mice. These subspecies included closely related populations from similar, contiguous habitats, as well as very divergent subspecies that had long been isolated in dissimilar habitats. In general, the benefits of increased heterozygosity outweighed the costs of disrupted gene complexes.

Predicting the Risk of Outbreeding Depression

The question of whether crossing geographically distinct populations of a species is likely to have beneficial or detrimental effects is an important conservation issue because many species now exist as a series of isolated or semi-isolated populations due to human activities. Inbreeding depression and loss of genetic diversity will ultimately contribute to the extirpation of many isolated populations unless gene flow

with other populations is reestablished. The introduction of individuals from other populations to improve reproductive fitness and restore genetic diversity can be an effective management strategy to aid the recovery of small inbred populations with low genetic diversity and has been successful in several natural populations including deer mice, wolves, mountain lions, greater prairie chickens, Swedish adders, desert topminnows, and several species of plants. However, before establishing gene flow between isolated populations, the risk of outbreeding depression should be evaluated.

Inadvertent crossing of populations that belong to separate species can result in outbreeding depression. This problem occurred with small antelopes called dik-diks, as zoos did not originally appreciate that the individuals in captivity belonged to more than one species. Thus, managers should make sure that two populations to be crossed belong to the same species. Fixed chromosomal differences between populations increase the probability of outbreeding depression so karyotyping of populations prior to crossing them is advisable. Predicting the likelihood of outbreeding depression resulting from adaptations to differing environmental conditions is more challenging. Because reproductive fitness is a quantitative character, Frankham and colleagues (Frankham *et al.*, 2011) recently provided theoretical and practical guidance in this area based on an extension of the breeder's equation:

$$\sum AD_t \sim h^2 \sum_{i=1}^t S_i (1 - 1/[2N_e])^{t-1}$$

where AD is the adaptive difference between two populations, h^2 the heritability of reproductive fitness, S_i the selection

Figure 5 Decision tree for predicting the risk of outbreeding depression when two populations are crossed.

differential in the i th generation, and N_e the effective population size. This work indicated that the degree of adaptive differentiation between two populations, and thus the probability of outbreeding depression if they are crossed, is an increasing function of four factors: (1) the selection differential, which increases with the difference between the environment to which the population was previously adapted and the current environment or environments of the populations to be crossed; (2) the heritability of the traits involved (which depends on the genetic diversity in the populations); (3) the effective population size (which is almost always smaller than the actual population size); and (4) the number of generations the populations have been separated. Calibration of the equation with data from the literature indicated that thousands of generations are required before populations isolated in the same environment begin to develop reproductive isolation but only dozens of generations are required if the populations are adapting to differing environments.

Based on these ideas, Frankham and colleagues developed a decision tree to assess the risk of outbreeding depression if two populations are crossed (Figure 5). Applying the tree to known cases successfully predicted the occurrence of outbreeding depression. The questions are based on the findings that small populations whose taxonomy is well-studied and generally accepted, that exhibit no fixed chromosomal differences, have experienced gene flow between the populations within the past 500 years, and inhabit similar environments, or have been in different environments for less than 20 generations have little risk of exhibiting outbreeding depression if crossed. In such circumstances, establishing gene flow between the populations is likely to have beneficial genetic and demographic consequences. Conversely, if the two populations belong to separate species, or exhibit fixed chromosomal differences, or have been isolated for 500 years or longer, or have been living in significantly differing environments for more than 20 generations, there is a modest to high risk of outbreeding depression if the populations are crossed. However, even when crosses of populations result in outbreeding depression, it will not be a long-term phenomenon

unless F1 individuals are sterile or have very low fitness, as natural selection will act on the extensive genetic variation in the hybrid population, resulting in better adaptation to its environment.

Landscape Genetics

Andrew Storfer, Washington State University, Pullman, WA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Analysis of molecular variance Similar to the statistical analysis of variance (ANOVA), but involves partitioning of molecular genetic data in different groups (e.g., within and among populations) based on hierarchical sampling procedures.

Extent Generally used in landscape ecology, referring to the overall size of a study area.

Functional connectivity Describes the processes of dispersal and gene flow of organisms among habitat patches.

Gene flow Refers to the movement of organisms among populations or locales followed by successful breeding event(s), resulting in the transfer of alleles from one population to another.

Grain Generally used in landscape ecology, referring to the spatial scale of individual observations.

Least-cost path A line (vector) of 'least resistance' is generated between two observation points. The resistance refers to a resistance surface, or cost grid in a landscape matrix, which is parameterized according to some

understanding of species' dispersal habits. The least-cost distance can be expressed in terms of geographic distance or total resistance along this path.

Mantel test A statistical test of the correlation between two matrices; in landscape genetics, these are a geographic and genetic distance matrix. Significance of the correlation is determined by randomly permuting the values in the rows and columns of the matrices to create a distribution of values to which the observed value can be compared.

Spatial autocorrelation Observations are not independent identically distributed, but are correlated over some distance in space. Positive autocorrelation indicates that nearby values are similar; negative autocorrelation indicates that nearby values are dissimilar.

Structural connectivity Generally refers to the distance between habitat patches and the nature of the intervening landscape matrix.

Tessellation A pattern of nonoverlapping polygons is used to partition the area leaving no gaps. In landscape genetics, tessellation is generally used to create polygons around each point where genotypes are collected.

Introduction

An increasing goal of ecology and evolutionary biology is to understand spatial patterns of genetic variation. However, until recently there have been both technological and analytical gaps between the fields of landscape ecology and population genetics to test the influence of spatial processes on population genetic structure (Manel *et al.*, 2003). That is, whereas landscape ecology improved greatly in its ability to understand *structural connectivity* of landscapes with advances in geographic information systems (GIS) and remote sensing, understanding *functional connectivity* among biological populations remained a challenge because of difficulties associated with accurately estimating migration rates (e.g., low recapture probabilities or estimating breeding without dispersal; Holderegger and Wagner, 2008). However, our ability to obtain high resolution genetic data has dramatically increased, but population genetics had been focused on estimating functional connectivity (i.e., via estimating gene flow, which incorporates dispersal and breeding among populations), with little regard to structural connectivity of the intervening habitat matrix between populations. Landscape genetics emerged as an interdisciplinary analytical framework to bridge this gap (Holderegger and Wagner, 2008; Manel *et al.*, 2003) by drawing on analysis methods from landscape ecology, spatial statistics, geography, and population genetics to "...explicitly quantify the effects of landscape composition, configuration and matrix quality

on gene flow and spatial genetic variation" (Storfer *et al.*, 2007).

Whereas population genetics studies had previously been limited in spatial inference to tests of isolation-by-distance (IBD), landscape genetics studies test explicitly the relative influence of landscape and environmental features on gene flow, genetic discontinuities (Guillot *et al.*, 2008) and genetic population structure (Manel *et al.*, 2003). This area of inquiry has met with early success, as landscape genetic models generally provide a more complete picture of population genetic structure by typically explaining a significantly higher proportion of variation in gene flow than classic, straight-line Euclidean IBD models (Figure 1; Storfer *et al.*, 2010). Further, recent simulation studies have shown that a variety of landscape genetics techniques were able to detect the simulated scenario with relatively high power and accuracy (Balkenhol *et al.*, 2009a; Cushman and Landguth, 2010; Murphy *et al.*, 2008). As a result, understanding landscape effects on functional (genetic) connectivity can provide insight into fundamental biological processes such as: metapopulation dynamics, (ecological) speciation, and ultimately limits to species' geographic distributions.

The integrative approach of landscape genetics has tested both basic and applied research questions, including: identifying barriers to dispersal (Guillot *et al.*, 2008; Latch *et al.*, 2008; Manni *et al.*, 2004), modeling functional connectivity across different spatial scales (Murphy *et al.*, 2010; Rasic and Keyghobadi, 2012), inferring the effect of landscape change

Figure 1 Comparison of straight-line Euclidean distance model (a) with a landscape model that minimizes dispersal costs through wetlands (b). (a) A topographic map of Northern Yellowstone National Park. Black stars represent sampling localities. Green represents forest cover and blue represents streams. Red lines are Euclidean (i.e., straight line map) distances between sites. (b) Same as (a), except red lines are least-cost distances that minimize costs of paths through wetland areas.

(Wagner *et al.*, 2006; Wang *et al.*, 2008), estimating source–sink dynamics (Lowe *et al.*, 2006; Martinez-Solano and Gonzalez, 2008), predicting spread of disease (Biek and Real, 2010), testing whether current spatial genetic patterns are correlated with past landscape change (Spear and Storfer, 2008), and estimating the distribution of adaptive genetic variation across habitat gradients (Joost *et al.*, 2007; Manel *et al.*, 2010a; Segelbacher *et al.*, 2010).

Indeed, due to the wide variety of applications that landscape genetics offers, interest has burgeoned in recent years, and the number of publications is increasing. Researchers new to landscape genetics will quickly note that there are numerous ways to design a study, as well as multiple analytical frameworks and methods. As with any rapidly growing field that integrates previously disparate (sub-)disciplines, landscape genetics has faced challenges with: interdisciplinary communication, the integration of rapidly developing new analytical techniques and software, as well as, integrating and interpreting multiple analysis methods in a single study (Balkenhol *et al.*, 2009b; Holderegger and Wagner, 2008; Storfer *et al.*, 2007). There are several other insightful reviews that have summarized the field as well as its challenges (e.g., Balkenhol *et al.*, 2009a; Holderegger and Wagner, 2006, 2008; see a special issue of *Molecular Ecology* published in September, 2010). As such this review is not meant to be exhaustive, but rather to complement previous reviews by: (1) emphasizing the importance of having a robust study design; (2) discussing some of the most prevalent analytical frameworks; (3) summarizing the major insights that have come from landscape genetics studies to date; and, (4) highlighting some of the current and future challenges facing the discipline.

Study Design and Sampling

A recent review showed that only about one-third of landscape genetics studies had a clear sampling design (Storfer *et al.*, 2010). Perhaps this is not surprising given the relative youth of landscape genetics as a field and the fact that population genetics studies historically tended to rely on opportunistically collected samples (e.g., those obtained along roadsides; Storfer *et al.*, 2007). Because analyses typically tested IBD, sampling schemes tended to be hierarchical, focusing on sampling at localities ranging in (Euclidean) distance from one another. At the time, these sampling designs were sufficient to estimate genetic neighborhood sizes by using, for example, Analysis of Molecular Variance (or AMOVA; Peakall and Smouse, 2006) to partition genetic variance within and among individuals, populations and larger designations. Tests of IBD were often carried out using Mantel tests to determine whether there were correlations between a pairwise genetic distance matrix (e.g., F_{ST} among discrete sampling localities) and a pairwise geographic (Euclidean) distance matrix (Foll and Gaggiotti, 2006).

Landscape genetics studies necessitate a dramatically different sampling approach because the goal is to test explicitly how landscape characteristics influence gene flow (Anderson *et al.*, 2010; Guillot *et al.*, 2009; Storfer *et al.*, 2007). That is, in contrast to traditional population genetics studies, landscape genetics studies are *explicitly spatial* and incorporate landscape data from, for example, GIS, remote sensing and weather stations in addition to genetic data such as allele frequencies (Manel *et al.*, 2003; Spear *et al.*, 2010; Storfer *et al.*, 2007, 2010). As a consequence, sampling designs should ideally be based on knowledge of the dispersal ecology of the study

organism to guide the spatial scale of the study area, as well as the resolution at which GIS and other landscape layer data are sampled (Anderson *et al.*, 2010). Ecological data should include data on home range sizes, migration distances and geographic estimates of population size to guide both the *grain* and *extent* of spatial sampling scales. The grain size at which landscape data are collected should be smaller (e.g., remote sensing data in the USA often is at 30 m resolution) than estimated home range sizes or dispersal distances (Anderson *et al.*, 2010; Fortin and Dale, 2005). Sampling at a grain size that is too large or small may result in failure to capture the range of variation in an environmental (e.g., precipitation) or landscape variable (e.g., elevation), resulting in over- or under-estimation of the influence of that variable on gene flow (Storfer *et al.*, 2007). The extent of the overall study area should be at least as large as the anticipated spatial population size, preferentially with a buffer included (Anderson *et al.*, 2010) to minimize the possibility that gene flow from outside the study area could overwhelm that which occurs within the study area (Cushman and Landguth, 2010).

Ecological data of habitat preferences and aversions can also be quite useful for guiding which GIS layers will be most relevant for the study organism. For example, habitat suitability modeling can inform parameterization of GIS layers, such as for *least cost path* analysis (Figure 1) to assess landscape effects on genetic structure (Wang *et al.*, 2008). Generally, researchers should strive to capture the range of variation in landscape features that are hypothesized to be important, and consequently stratified sampling designs are generally preferred (Storfer *et al.*, 2007). However, whether the most appropriate sampling design is systematic or random may depend on the distribution of the study organism; for example, systematic sampling is most appropriate for species with relatively even and continuous distributions (Harrison and Dunn, 1993; for a detailed discussion on sampling design considerations, see Storfer *et al.* (2007)). Nonetheless, if ecological data on dispersal and habitat use are lacking, data on closely related species can be used to guide sampling grain, extent and landscape variables to be used in statistical models.

Once a sampling strategy has been designed, researchers typically collect geo-referenced (e.g., by using Global Positioning System (GPS)) tissue samples and commonly use hypervariable nuclear deoxyribonucleic acid (DNA) markers (most commonly microsatellites or amplified fragment length polymorphisms (AFLPs); Storfer *et al.*, 2010) across multiple loci to generate a distribution of allele frequencies. Then, usually a genetic distance matrix is computed among sampling localities using analogs of Wright's F-statistics (Wright, 1951) or other distance measures, including chord distance (D_C ; Cavalli-Sforza and Edwards, 1967), Nei's distance (D_N ; Nei, 1972), or proportion of shared alleles (D_{PS} ; Bowcock *et al.*, 1994). These methods are most appropriate for species that have clustered distributions, and for species with relatively continuous distributions, such as many plant species, a growing number of individual-based distance methods are being developed (e.g., Manel *et al.*, 2007; Murphy *et al.*, 2008). Alternatively, allele frequencies themselves are used to cluster individuals among populations, as in assignment tests (Francois and Durand, 2010; Guillot *et al.*, 2008; Pritchard *et al.*, 2000). In turn, researchers test for correlations of

hypothesized landscape variables with allele frequency distributions or genetic distances. The highlight here is on the most common analytical frameworks to achieve this goal below, which include use of Mantel (and partial Mantel) tests, barrier detection methods (including use of assignment tests), use of resistance surfaces, and network-based approaches. Other, less commonly used approaches have included ordination and multiple matrix regression, which will be covered briefly.

Analytical Frameworks

Mantel Tests

Mantel or partial Mantel tests remain a predominant way to test for correlations between a matrix of genetic distances and a matrix or matrices of geographic or landscape distances (Storfer *et al.*, 2010). Significant positive correlations with a particular landscape matrix and a genetic distance matrix suggest that a given landscape variable impedes gene flow, whereas significant negative correlations suggest the variable enhances gene flow. Partial Mantel tests, in particular, quantify the correlation between two distance matrices, while controlling for the effects of a third covariant matrix. In landscape genetics, partial Mantel tests are conducted to test the significance of correlations with a genetic distance matrix and usually several different landscape distance matrices. Causal modeling represents a relatively recent application of partial Mantel tests in landscape genetics (Cushman *et al.*, 2006). Causal modeling is used to test a variety of competing hypotheses as to which landscape factors best explain genetic structuring among groups, locales or populations. With a series of partial Mantel tests, competing hypotheses and the statistical predictions of each can be tested, with all statistical predictions met by only the hypothesis with the strongest support (Legendre and Troussellier, 1988). An example is a study of black bears in Northern Idaho, where the influence of a variety of different landscape variables was tested, including land cover, slope, elevation, and roads. Causal modeling of seven competing organizational models showed support for only one, which included only the influence of land cover and elevation on black bear genetic structure (Cushman *et al.*, 2006).

Debate continues about the use of partial Mantel tests in landscape genetics. Some researchers question the appropriateness of permutation procedures for significance testing among multiple matrices with non-independent or multicollinear variables (Castellano and Balleto, 2002; Rousset, 2002). In addition, a comparison of statistical methods (Balkenhol *et al.*, 2009a) showed that partial Mantel tests had lower power and higher type I error than other analyses, such as partial canonical correspondence analysis (CCA), and Bayesian inference of immigration rates (Faubet and Gaggiotti, 2008). Yet, others argue that although caution of high type I error of partial Mantel tests is warranted, this error is not inherent in using the test *per se* (Cushman and Landguth, 2010). Rather, high error rates in Mantel tests can be caused by correlations of expectations from alternative hypotheses (e.g., a particular landscape feature could act as an absolute barrier vs. providing an area of high resistance to dispersal; Cushman

and Landguth, 2010). Together, these studies warrant caution regarding use of partial Mantel tests, careful construction of hypotheses, and the need to use alternative statistical tests to confirm partial Mantel results.

Barrier Detection

As of 2010, approximately half of the landscape genetics studies focused on understanding barriers to gene flow using a variety of approaches (Storfer *et al.*, 2010). Interest in barriers to gene flow is broad, spanning from understanding basic landscape features that generate genetic population structure, to understanding the conservation implications of anthropogenic development (e.g., roads and dams). Early studies sampled on both sides of a putative barrier and compared genetic distance across the barrier with samples taken at similar distances in continuous habitat (Storfer *et al.*, 2007). If significantly decreased gene flow was found across the putative barrier and not the continuous habitat, it was concluded that the landscape feature was, in fact, a barrier. An example was a study that showed that a California highway acted as a barrier to gene flow for both bobcats and coyotes (Riley *et al.*, 2006).

More recently, methods in landscape genetics and spatial statistics have together allowed both more quantitative and spatially explicit ways of investigating potential barriers such as mountains, as well as ways to detect breaks in genetic continuity caused by less obvious or even cryptic landscape features, such as changes in moisture patterns across a study area (Storfer *et al.*, 2007). One approach for detecting changes in allele frequencies in space is Wombling (Barbujani *et al.*, 1989; Womble, 1951). Wombling has been used to identify spatial locations of abrupt changes in allele frequencies by quantifying local variability in allele frequencies (Cercueil *et al.*, 2007). The software WOMBSOFT (Crida and Manel, 2007) utilizes local polynomial regressions to estimate these genetic changes, as well as a binomial test for significance of each genetic break. A recent example is a study of Giant pandas in China, where a Wombling analysis showed genetic breaks between the Xiaoxiangling and Daxiangling Mountains (Zhu *et al.*, 2011). Another approach is using Monmonier's maximum difference algorithm, which creates a break line through the vectors between a network of sampled populations or individuals (Monmonier, 1973). Essentially, the Monmonier algorithm estimates the largest changes in allele frequencies along this break line, and thereby allows inference of barriers in these locations. Noted drawbacks of this method include dependence on the initial sampling design, as well as an *a priori* definition of the number of genetic groups present in the study area (Guillot *et al.*, 2009).

One way to circumvent the necessity of predefining the number of (genetic) populations is by using assignment tests. Assignment tests are most commonly used to determine the most likely number of genetic clusters (or K ; i.e., populations) based on allele frequencies among samples using a Bayesian approach and Monte Carlo Markov Chain (MCMC) optimization (Pritchard *et al.*, 2000; Guillot *et al.*, 2008). Researchers should be aware that K is estimated in a variety of different ways, depending on the assumptions of the method, such as whether there is admixture or not, and the software

used (Rowe and Beebe, 2007; Francois and Durand, 2010; Guillot *et al.*, 2009). Barriers or edges are commonly inferred when genetic clustering coincides with one or more geographic features consistent with those that would impede movement of the study organism (Figure 2). For example, the program GENELAND (Guillot *et al.*, 2008) was developed as a spatially explicit assignment-based approach to determine the number of genetic clusters (i.e., K) present in a dataset. *Tessellation* is used to construct a series of polygons that denotes the boundaries of the genetic clusters in space, independent of the sampling sites (Guillot *et al.*, 2008). Barriers can thus be inferred to coincide with the spatial locations of the polygon edges that delineate the genetic clusters. An individual-based assignment test method provides another approach for detecting genetic discontinuities among samples while avoiding population delineation (Manel *et al.*, 2007). This method generates a spatially referenced probability map for finding the genotype of a particular individual using a moving window approach. A mean slope for all individual probability maps is calculated, and population boundaries are identified by areas of high mean slope (Manel *et al.*, 2007). A comparison of assignment tests and other edge detection methods, including Wombling and Monmonier's algorithm, showed that assignment tests generally perform better on both simulated and empirical data (Safner *et al.*, 2011). Reviews of the applications of, and statistical issues with, assignment tests can be found in Manel *et al.* (2005), Guillot *et al.* (2009), and Francois and Durand (2010).

Resistance Surfaces

Another major way to assess effects of landscape features on the spatial distribution of genetic variation is with the use of resistance surfaces (Spear *et al.*, 2010). Generally, resistance surfaces are estimated by assigning values to each landscape variable or environmental feature contained in a spatial layer of a raster GIS environment (Spear *et al.*, 2010). Higher assigned values translate to greater hypothesized resistance to gene flow by that particular variable, whereas lower values suggest lower resistance. Thus, each grid square (e.g., 30 m or 1 km) in a GIS is assigned a cumulative value based on hypothesized habitat use and movement through each of the landscape variables contained in that grid square. The resistance surface comprised of all grid squares that make up the intervening habitat matrix between sampling localities across a study area (Figure 3). Rarely do researchers have direct estimates of dispersal and habitat use to parameterize such surfaces, and therefore assignment of resistance values to each landscape feature remains a challenge for modeling resistance surfaces (Spear *et al.*, 2010). As a result, the majority of resistance surfaces are constructed using subjective methods; a recent review suggested only approximately one-fourth of studies used nongenetic field data, such as radio-telemetry data or direct movement studies, to inform resistance assignment values (Spear *et al.*, 2010). One way to deal with the problem of subjectively assigning resistance values is by assigning a range of values to each landscape variable, thereby generating a variety of surfaces that comprise alternative hypotheses. Then, the multiple surfaces can be statistically

Figure 2 Represents a barrier detection method using a combination of Bayesian clustering analysis and overlay approach in Olympic National Park, USA. (a) Bayesian clustering output using the software STRUCTURE (Pritchard *et al.*, 2000) showing two genetic groups (red and green) identified from multiple sampling locations. Each bar is an individual, and the proportion of its genotype assigned to either population is shown by the proportion of the bar that is red vs. green. (b) Identification of barrier using overlay approach. Letter and number coded dots on map represent sampling localities. Red and green circles correspond to identified populations using Bayesian clustering. Black line is Hurricane Ridge, a visually identified barrier between the green and red genetic clusters.

compared as to which best fits the genetic distance data (Cushman *et al.*, 2006; Cushman and Landguth, 2010). Another potential solution is to incorporate habitat suitability maps into estimation of resistance surfaces by using presence/absence data for the study species (Wang *et al.*, 2008).

Two major modeling frameworks have been used to convert resistance values into measures of population connectivity – least-cost paths and circuit-based analyses. Least-cost paths are based on the underlying assumption that costs, in terms of cumulative resistance values between populations, are minimized such that individuals tend to move along an optimal path (Figure 1(b); Adiransan *et al.*, 2003). As an example, Epps *et al.* (2007) used a least-cost based analysis to find that topographic distance explained a significantly higher proportion of variation in gene flow than Euclidean distance alone for desert bighorn sheep. Least-cost paths have been criticized because they are based on the potentially unrealistic assumption that individuals “know” *a priori*, which is the least costly path to take during dispersal events. One suggestion to overcome this problem is to consider multiple least-cost paths together in order to delineate a zone of probable movement (Rayfield *et al.*, 2010).

Circuit theory-based models simultaneously integrate all possible pathways that connect populations, while still assuming that genetic distance is positively correlated with resistance (McRae, 2006). The software CIRCUITSCAPE is used to estimate overall significance of the resistance surfaces in explaining genetic structuring among samples, along with tests of significance of individual landscape variables (Shah and McRae, 2008). The latter approach was shown to perform better, with a higher proportion of variation in gene flow explained when both least-cost path models and circuit theory-based models were applied to empirical datasets of mahogany and the wolverine (McRae and Beier, 2007). More recently, it has been suggested that least-cost paths may perform better on smaller spatial scales (Anderson *et al.*, 2010). Nonetheless, given the assumptions inherent in least-cost path and circuit theory-based (i.e., that all possible paths are influence movement in some way) analyses, caution should be used when applying either analysis to understand population-level connectivity. Spear *et al.* (2010) provide guidelines and potential solutions for addressing these problems, including use of computer simulations or network-based approaches.

Figure 3 Steps to building a resistance surface using multiple landscape features. (a) Road through the study area. (b) Map of canopy cover in the area; blue indicates low cost areas, red indicates high cost, and green triangles represent sampling locations. (c) Map of elevation in the study area; red indicates high elevation and high cost, yellow shows intermediate cost and blue shows low cost. (d). Multivariate resistance surface indicating cumulative costs from (a)–(c).

Graph Theory and Network Analyses

Graph theory can be applied in population and landscape genetics by treating localities or individuals as nodes and connections between them as edges as in a network (Dyer and Nason, 2004). The strength of each edge is essentially proportional to the rate of gene flow between the two nodes that it connects (as estimated by their genetic covariance), and a complete lack of an edge suggests significant population subdivision (Dyer and Nason, 2004; Dyer, 2007). Originally, this framework was applied using the software POPGRAPH, whereby genetic structure was estimated across all nodes simultaneously, and users could test for population subdivision as indicated by significant deficiencies of edges between user-defined groups of nodes (Figure 4; Dyer and Nason, 2004). An empirical study that used this approach showed that, taken together, high elevation sites were significantly genetically differentiated from low elevation sites for the long-toed salamander (Giordano *et al.*, 2007).

Network analyses have been applied in the graph-theoretic approach to model functional connectivity (Garroway *et al.*, 2008; Murphy *et al.*, 2010). In addition to understanding overall connectivity of nodes and substructure across an entire network, analyses can also determine the properties of a specific node. Aside from the degree centrality of a node, which is an estimate of connectivity based on the number of connections it has to other nodes, other commonly evaluated properties include eigenvector centrality and betweenness (Garroway *et al.*, 2008). Eigenvector

Figure 4 Example of a network using a graph-theoretic approach. Symbols indicate different sampling localities (i.e., nodes); shape size is proportional to the amount of observed genetic structure. Different shapes represent different genetic clusters, and lines between shapes (i.e., edges) represent significant genetic exchange between the two sampling localities that the lines connect.

centrality incorporates both direct and indirect connectivity of particular nodes, thereby weighting well-connected nodes more heavily than those that are less connected. Betweenness is the number of shortest paths that a particular node

(or edge) lies on. Assuming interactions within a network generally follow shortest paths, betweenness generally measures the importance of a particular node in terms of how often individuals must path through it (i.e., how much of a bottleneck it creates; Garroway *et al.*, 2008). Estimation of these nodal properties can translate into the understanding of the relative importance of a particular population or locality in sustaining an entire network or metapopulation. An example of a network analysis was conducted with fishers (*Martes pennanti*) in Ontario, Canada, where nodes were highly clustered and generally had short path lengths, suggesting high connectivity and high resiliency to loss of any particular node (Garroway *et al.*, 2008). Analyses also showed animals tended to move from high- to low-quality habitat, as well as evidence of cryptic population structure not indicated with traditional population genetic analyses (Garroway *et al.*, 2008). A later study incorporating use of resistance surfaces with network-based analyses showed that road density, snow depth, and river density all impeded gene flow (Garroway *et al.*, 2011).

Gravity models have also been adapted for use in network analyses of functional connectivity in a landscape genetics study (Murphy *et al.*, 2010). These models are based on Newton's law of gravitation and predict flow from a site within a network; such models have been historically used in modeling economic trade routes, for example (Willig and Bailey, 1979). Essentially, these models incorporate the influence of at-site (node) and between-site (edge) characteristics on number of trips through a network (Anderson, 1979). In a landscape genetics study, some measure of genetic distance is used as the response variable as opposed to number of trips (Murphy *et al.*, 2010). A gravity model-based approach yielded evidence of source-sink dynamics among localities of the Columbia spotted frog (*Rana luteiventris*), whereby presence of predatory fish at sites reduced connectivity but growing season and site productivity were correlated with increased connectivity (Murphy *et al.*, 2010).

Overall, the network analytical framework holds much promise for application in landscape genetics. Typically, landscape genetics studies have focused solely on the influence of between-site (i.e., edge) characteristics on functional connectivity among populations. However, network-based analytical approaches also yield information about the influence of at-site characteristics on gene flow and population genetic structure. These data can be quite useful for conservation and management, for example, by emphasizing protection of sites with high degrees of centrality. These approaches also obviate the need for *a priori* assumptions of the number of populations in a sample (Garroway *et al.*, 2008). In addition, network-based approaches are 'model free' (Dyer and Nason, 2004), in the sense that the significance of observed networks can be obtained by comparisons with fully saturated or randomly generated networks (Garroway *et al.*, 2008).

Ordination and Regression

Ordination (e.g., principal components analysis, or PCA, canonical correspondence analysis or CCA) has also been shown to be a powerful technique for investigating the spatial

arrangement of genotypes on a landscape (Balkenhol *et al.*, 2009a). Because space can explicitly be included in CCA (Borcard *et al.*, 1992), the analytical method can be used to identify correlations between allele frequency distributions and gradients in environmental variables (ter Braak and Verdonschot, 1995). Recently, it was shown that partial CCA was effective in accounting for spatial effects through the incorporation of coordinates as covariates (Balkenhol *et al.*, 2009a). A simulation study that compared CCA with several other statistical methods, including Mantel tests and partial Mantel tests, showed the method had higher power to detect landscape effects on spatial genetic structuring (Balkenhol *et al.*, 2009a). Despite its potential, however, ordination has most often been used in empirical studies to cluster the genetic data without including landscape variables (Storfer *et al.*, 2010).

Linear regression or general linear models have also commonly been used in landscape genetics studies. However, these methods should be cautiously used because they are generally inappropriate in situations of substantial autocorrelation (i.e., spatial non-independence of genetic and landscape data), unless significance testing relies on data permutation approaches (Fortin and Dale, 2005). Potential alternatives that attempt to account for non-independence and *spatial autocorrelation* are classification and regression tree (CART) models (Murphy *et al.*, 2010), geographically weighted regression (Spear and Storfer, 2008), and network models (Garroway *et al.*, 2011; Murphy *et al.*, 2010).

Multiple matrix regression techniques also hold promise, and one approach that has been applied in landscape genetics studies is multiple regression of distance matrices (MRDM; Legendre *et al.* (1994)). This procedure involves a stepwise regression of a dependent (genetic) distance matrix and multiple independent pairwise (landscape) matrices. Landscape data are pairwise estimates of spatial separation between sampling points or localities. An MRDM analysis was used to understand landscape influence on genetic structure of the bush cricket, *Metrioptera roeseli*, whereby historic landscape patterns (50 years old) explained genetic structure better than current landscape pattern (Holzhauer *et al.*, 2006). Relative to other methods, including Mantel tests and Bayesian analyses, MRDM had high power and low type I error rates in a simulation study (Balkenhol *et al.*, 2009a).

Research Insights

General Trends

The majority of landscape genetics studies have lacked explicit hypotheses to test the influence of landscape variables on genetic connectivity (Storfer *et al.* (2010); but see Cushman *et al.* (2006) and Wang and Summers (2010)). For example, the most commonly studied feature has been the influence of putative barriers, which have frequently been revealed by visual inspection of genetic clusters for spatial coincidences of cluster boundaries with landscape features (e.g., Figure 2). However, given that landscape genetics is a relatively young discipline (Manel *et al.*, 2003), it is not surprising that initial studies have often been exploratory as opposed to hypothesis-

driven. That is, a basic understanding of gene flow and genetic population structure is necessary before testing specific hypotheses related to the influence of landscape variables. This is particularly true for species for which little ecological data regarding dispersal and habitat use are available. Nonetheless, given the multitude of recent theoretical developments and the utility of simulation studies and software (e.g., Cushman and Landguth, 2010; Epperson *et al.*, 2010), landscape genetics should move toward testing specific hypotheses of how environmental and landscape features influence the spatial distribution of genetic variation (Balkenhol *et al.*, 2009a; Manel *et al.*, 2010a; Storfer *et al.*, 2010).

In addition, landscape genetics studies have been largely confirmatory, for example finding support for the influence of variables intuitively thought to be gene flow barriers, such as ridgelines, rivers, or roads. Again, given that the discipline is relatively new, confirmation has largely been positive, demonstrating that spatial models that include landscape features most often explain a significantly higher proportion of variation in gene flow than isolation by (Euclidean) distance models. Nonetheless, some studies showed no improvement in models explaining gene flow despite the inclusion of landscape variables (e.g., Bolliger *et al.*, 2011; Rieux *et al.*, 2011), and several studies showed evidence of counterintuitive effects of landscape features. For example, although rivers were thought as an *a priori* barrier to gene flow among populations of blotched tiger salamanders (*Ambystoma tigrinum melanostictum*) in Yellowstone National Park, they were actually found to facilitate gene flow likely due to the homogenizing influence of recurrent, occasional floods (Spear *et al.*, 2005). Similarly, flooding apparently increased gene flow among populations of the herb, *Primula sieboldii* (Kitamoto *et al.*, 2005). In addition, contrary to predictions, postfire-regenerated shrub habitat in Yellowstone National Park was shown to facilitate gene flow among tiger salamanders (Spear *et al.*, 2005) and boreal toads (*Bufo boreas*; Murphy *et al.*, 2010). Although previously thought of as an impediment to gene flow, shrubs probably facilitate amphibian dispersal by providing better shade and thereby desiccation protection than forested habitat with taller trees.

Other general trends included a focus on temperate versus tropical areas, despite the fact that tropical areas are hotspots of biodiversity (Myers *et al.*, 2000), and increasing targets of conservation efforts (Carnaval *et al.*, 2009). Biases also existed in the use of molecular markers, using primarily microsatellites in animals, with AFLPs used primarily in plants (Holderegger *et al.*, 2010; Storfer *et al.*, 2010). In addition, most studies focused on a single species, and the majority occurred on vertebrate species in terrestrial habitat (Storfer *et al.*, 2010). Overall, there are also fewer plant studies than those of animals, largely because of general assumptions implicit in the most broadly used analytical frameworks that include landscape distance and resistance (Holderegger *et al.*, 2010). Nevertheless, plants are well-suited for studies of barriers to gene flow, as well as for understanding the spatial distribution of adaptive genetic variation (Holderegger *et al.*, 2010). Approximately 80% of landscape genetics studies focused on identification of barriers (50%) and understanding the effects of landscape features on genetic variation (30%), with the effects of anthropogenic development and habitat use

also considered by many studies; generalities arising from these three research foci are discussed in the following three sections.

Identifying Barriers

Some of the most frequently considered barriers to gene flow in landscape genetics studies are linear terrestrial features, such as rivers and mountain ridges, roads, and edges created by anthropogenic habitat fragmentation. Rivers have been identified as a barrier to gene flow in several taxonomic groups including small mammals, turtles, deer, and fishers (Coulon *et al.*, 2006; Garroway *et al.*, 2008, 2011; Lugon-Moulin and Hausser, 2002; Mockford *et al.*, 2007), but may actually facilitate gene flow in amphibians (Spear *et al.*, 2005) and transgenic crops (Cureton *et al.*, 2006). Major ridgelines are barriers to gene flow in amphibians (Funk *et al.*, 2005; Giordano *et al.*, 2007) and meso-mammals (Zalewski *et al.*, 2009), but may not limit gene flow in small mammals (Lugon-Moulin and Hausser, 2002). Mountain ranges, as well as low-elevation valleys served as broad scale gene flow barriers to Mojave desert tortoises (Hagerty *et al.*, 2011). A large valley also served as a barrier to gene flow in the African acacia, *Senegalia mellifera* (Guajardo *et al.*, 2011). Although effects of some natural habitat features may be species-specific, roads and other human developments consistently impede gene flow for animals spanning several taxonomic groups, including carnivores (Millions and Swanson, 2007; Riley *et al.*, 2006), ungulates (Epps *et al.*, 2007; Kuehn *et al.*, 2007; Perez-España *et al.*, 2008), and amphibians (Manier and Arnold, 2006; Murphy *et al.*, 2010).

Clearly defined linear barriers are also present in aquatic systems. Dams are major barriers to gene flow in aquatic species such as fish, even when ladders and other mitigation features designed to facilitate dispersal across the dam are in place (Deiner *et al.*, 2007; Raeymaekers *et al.*, 2008; Skalski *et al.*, 2008; Taylor *et al.*, 2003; Wofford *et al.*, 2005). Also, natural physical barriers such as waterfalls have been important for shaping genetic structure patterns in yellow perch (*Perca flavescens*; Leclerc *et al.*, 2008), various trout species (Deiner *et al.*, 2007; Taylor *et al.*, 2003; Whiteley *et al.*, 2006; Wofford *et al.*, 2005), and mountain whitefish (*Prosopium williamsoni*; Whiteley *et al.*, 2006). Anthropogenic development adjacent to waterways, such as timber harvest can change water chemistry, temperature, dissolved oxygen levels and light penetrance, thereby acting as a barrier to fish gene flow (Wilcock *et al.*, 2007). Further, fragmentation of breeding habitat may have an additive effect with physical structures such as dams (Leclerc *et al.*, 2008) and roads (Balkenhol and Waits, 2009).

Other, less obvious features can act as barriers to gene flow. For example, unsuitable natural habitat such as savanna acts to fragment lemur populations (Radespiel *et al.*, 2008) and dry grassland habitat increases genetic structuring among salamander populations (Rittenhouse and Semlitsch, 2006). Cryptic barriers to gene flow, such as climate gradients, have been shown to produce unexpected sharp breaks in genetic structure possibly due to species' environmental tolerance limits. An example can be found among salt-water habitat

where cetaceans have abrupt discontinuities in genetic structure (Fontaine *et al.*, 2007). In some cases, the additive effects of several landscape features of low permeability can cause detectable differentiation even among weakly genetically structured populations, such as the combined influence of a river, highways, and canals on roe deer (*Capreolus capreolus*) gene flow in France (Coulon *et al.*, 2006).

Identification of barriers to gene flow can help predict the geographic nature of disease spread or assist with management (Biek and Real, 2010). Barriers to parasite dispersal depend on mode of spread. Directly transmitted parasites are generally dependent on dispersal of the host, and often have smaller genetic neighborhoods than vectored parasites or wind-borne parasites (Biek and Real, 2010). Rivers have commonly been shown to be a barrier to host movement and thereby disease dispersal, from chronic wasting disease in deer (Blanchong *et al.*, 2008), to limiting movement of various primate species and consequently the spread of simian immunodeficiency virus (SIV) (Gagneux *et al.*, 2001). However, a study of two rivers showed that one served as a barrier to raccoon gene flow and consequent rabies spread, whereas rabies persistently spread across a different river (Cullingham *et al.*, 2009). As a result, caution should be used in assuming host genetic structure correlates with disease structure and spread (Biek and Real, 2010). Nonetheless, this type of information facilitated efficient rabies control strategies, with focused deployment of vaccinated raccoon bait where landscape variables were shown to facilitate, rather than act as barriers to, dispersal and gene flow (Real and Biek, 2007).

Influence of Landscape Variables Spatial Genetic Variation

Second to the study of barriers, studies of the influence of landscape variables on spatial genetic variation comprised the largest number of studies (Storfer *et al.*, 2010). Topographic relief was shown to restrict gene flow in many terrestrial species, including most species of amphibians (Funk *et al.*, 2005; Murphy *et al.*, 2010; Spear and Storfer, 2008), small mammals including voles (Berthier *et al.*, 2006), red deer (*Cervus elaphus*; Pérez-Espona *et al.*, 2008), wax palms (*Ceroxylon echinulatum*; Trénel *et al.*, 2008) and golden-brown mouse lemurs (*Microcebus ravelobensis*; Radespiel *et al.*, 2008). Elevational gradients limited gene flow between high- and low-altitude populations of Columbia spotted frogs (*R. luteiventris*; Funk *et al.*, 2005) and long-toed salamanders (*Ambystoma macrodactylum*; Giordano *et al.*, 2007). However, landscape features had little effect on gene flow and population genetic structure of damselflies (Wellenreuther *et al.*, 2011) and several species of birds (Barr *et al.*, 2008; Petren *et al.*, 2005). However, some populations of red-tailed hawks (*Buteo jamaicensis*) genetic structuring occurred across some mountain ranges, but not others (Hull *et al.*, 2008). Instead, habitat preferences were even more important for explaining red-tailed hawk gene flow, with limited dispersal between Mediterranean central California habitats and more xeric inland western and southern habitats (Hull *et al.*, 2008).

Seasonality can also affect gene flow. As an example, flowering time at different altitudes was significantly affected by timing of snowmelt, and flowering segregation, in turn, leading to fine-scale spatial genetic structuring in the alpine snowbed

herb, *Primula cuneifolia*, (Hirao and Kudo, 2004, 2008). Winter also affects genetic structure in fisher populations, as deep snow restricts gene flow (Garroway *et al.*, 2011).

In river and spring systems, landscape genetic models that included the drainage pattern, direction and speed of water flow best explained patterns of genetic structure in zooplankton (Michels *et al.*, 2001), brook charr (Angers *et al.*, 1999), and aquatic snails (Wilmer *et al.*, 2008). Also, dynamic and sporadic events like flooding were critical for explaining genetic structure (Wilmer *et al.*, 2008). The landscape variables of slope, elevation, and temperature were important predictor variables in multiple studies. For example, fish populations at higher elevations had lower levels of genetic diversity and lower levels of gene flow with other populations (Angers *et al.*, 1999; Castric *et al.*, 2001; Narum *et al.*, 2008), and gene flow was negatively correlated with change in elevation between sampling sites for the stream salamander, (*Gyrinophilus porphyriticus*; Lowe *et al.*, 2006). Precipitation was found to be important for genetic structuring among three Pacific salmon species (Olsen *et al.*, 2011). In contrast, water temperature explained the most variation in genetic structure among Atlantic salmon (*Salmo salar*) along the North American Atlantic coast (Dionne *et al.*, 2008) and steelhead trout in the Pacific Northwest (Narum *et al.*, 2008).

In marine environments, landscape genetic studies have demonstrated that genetic diversity and structure are often best explained by analyses that include ocean currents (blue whiting, *Micromesistius poutassou*; Was *et al.*, 2008, and kelp bass *Paralabrax clathratus*, Selkoe *et al.*, 2010). In other studies, ocean temperatures were the most important predictor variable of genetic structure in the sea urchin, *Centrostephanus rodgersii* (Banks *et al.*, 2007) whereas both temperature and salinity were key variables for explaining genetic structure patterns in Atlantic cod (*Gadus morhua*; Case *et al.*, 2005). In a multispecies analysis along the California coast, cumulative kelp cover, a measure of habitat quality, was the most important variable for explaining genetic diversity and structure in kelp bass, Kellet's whelk (*Kelletia kelletii*) and California spiny lobster (*Panulirus interruptus*; Selkoe *et al.*, 2010).

In sum, a wide variety of landscape variables have been tested for their influence on population genetic structure. In terrestrial systems, elevation, ridgelines, and topographic relief were often found to limit gene flow in terrestrial species. In aquatic species, drainage structure, slope, elevation, and temperature were frequently important explanatory variables. In marine species in particular, ocean currents have also been found to be important.

Tests of Anthropogenic Influence

Effects of anthropogenic land use change have been the focus of a large number of terrestrial and aquatic landscape genetic studies, and results have been mixed. Habitat fragmentation has reduced gene flow in many species, including: formica ants (Mäki-Petäys *et al.*, 2005), common frogs (*Rana temporaria*; Johannson *et al.*, 2005), alpine butterflies (*Parnassius smintheus*; Keyghobadi *et al.*, 2005), and golden cheeked warblers (*Dendroica chrysoparia*). For example, among fragmented populations of the forest herb, *Primula elatior*, lower genetic

variation was found in (developed) habitat patches less than 35 years old relative to those older than 35 years (Jacquemyn *et al.*, 2004). A study in fragments versus closed forest of Andean oak (*Quercus humboldtii*) also showed detrimental effects of anthropogenic habitat use on genetic variability (Fernandez and Sork, 2007). Further, urban areas acted as gene flow barriers for the alpine newt, *Mesotriton alpestris*, but forests acted as dispersal corridors, highlighting the importance of maintaining natural habitat (Emaresi *et al.*, 2011).

For multiple riverine systems, decreased gene flow and genetic diversity were correlated with the presence of anthropogenic landscape features. Dams, tunnels and weirs were found to impede gene flow in yellow perch (Leclerc *et al.*, 2008), several trout species (Costello *et al.*, 2003; Taylor *et al.*, 2003; Wofford *et al.*, 2005), and three-spined stickleback (*Gasterosteus aculeatus*; Raeymaekers *et al.*, 2008). Pulp mill impacts were also found to increase genetic structure in redbreast sunfish (*Lepomis auritus*; Theodorakis *et al.*, 2006) and three-spined stickleback (Raeymaekers *et al.*, 2008). Similarly, copper mine waste outputs restricted gene flow among populations of the saltwater kelp, *Lessonia nigrescens*, in Chile (Faugeron *et al.*, 2005).

However, no effects of fragmentation have been found for several other species, including: Amazon liverworts (*Radula flaccida*; Zartman *et al.*, 2006), the tree species, *Sorbus aucuparia* (Bacles *et al.*, 2004). In a Mexican *Heliconia* species, habitat fragmentation appeared to have little effect on genetic diversity, despite low levels of gene flow (Suarez-Montes *et al.*, 2011). In addition, habitat fragmentation caused by obvious anthropogenic barriers such as roads apparently did not affect gene flow in coyotes (*Canis latrans*); rather gene flow appeared restricted by breaks in habitat types, as well as natal site fidelity (Sacks *et al.*, 2004).

Fragmented landscapes did apparently affect habitat use during dispersal movements for some species highlighting the need to investigate more detailed hypotheses than effects on gene flow or genetic diversity, *sensu stricto*. For example, despite the fact that overall gene flow appeared unaffected in the yellow-footed antechinus, dispersal was reduced through agricultural landscapes (Lada *et al.*, 2008). In addition, gene flow remained high between primary and secondary growth (i.e., postharvest) forest fragments for the forest herb, *Geum urbanum*, but small populations were more genetically diverged than large populations (Vandepitte *et al.*, 2007). Gene flow of Rocky Mountain tailed frogs (*Ascaphus montanus*) more closely followed riparian corridors in deforested landscapes than naturally regenerated postfire landscapes (Spear and Storfer, 2010).

Discrepancies among habitat fragmentation studies may also result from an inability to disentangle the influence of contemporary versus historic landscape features on gene flow (Keyghobadi *et al.*, 2005; Pavlacky *et al.*, 2009; Storfer *et al.*, 2007). On the one hand, historical events could have long-term consequences and potentially confound inferences based on current landscape structure (Landguth *et al.*, 2010). Alternatively, effects of contemporary fragmentation may not be seen due to a lag time necessary for statistical detection. For example, Spear and Storfer (2008) examined correlations of current and historic patterns of timber harvest on Coastal tailed frog (*Ascaphus truei*) gene flow, which correlated strongly with harvest patterns from 20 years ago. This time lag may be

due to the speed in which timber harvest can alter landscape structure, as well as the long-generation time of tailed frogs, which could delay the detection of a genetic signature of reduced dispersal. Similarly, genetic structure was explained better by historical natural events, rather than current habitat fragmentation among populations of the Glanville fritillary butterfly (*Melitaea cinxia*; Orsini *et al.*, 2008). In contrast, contemporary deforestation explained more variation in genetic differentiation than a reconstructed pre-European settlement landscape for the rainforest dwelling logrunner (*Orthonyx temminckii*; Pavlacky *et al.*, 2009).

Overall, given the variability in effects of habitat fragmentation on genetic variation and gene flow, studies that test the effects of fragmentation should be conducted before conservation and management decisions are implemented. Anthropogenic features, such as deforestation, agricultural development, damming, and other types of waterway manipulation decreased gene flow or altered movement pathways in some species, but had little to no effect on others. Discrepancies among studies highlight the need for species-specific studies, as well as those that consider current versus historical effects on population genetic structure.

Challenges and Future Directions

Interdisciplinary Communication

It has been noted in several different reviews that because each of the subdisciplines involved in landscape genetics – population genetics, landscape ecology, and spatial statistics – has distinct terminology and analytical approaches, challenges arise associated with cross-disciplinary communication (Balkenhol *et al.*, 2009b; Holderegger and Wagner, 2006; Jacquery *et al.*, 2011; Storfer *et al.*, 2007, 2010). Recently, however, these challenges are being addressed. First, both a working group and a distributed graduate seminar were funded by the US National Center for Ecological Analysis and Synthesis (NCEAS) to bring diverse groups of researchers from the different disciplines together to collaborate and develop new analytical approaches. A major result of these efforts was a special issue of *Molecular Ecology* (September, 2010) focused on landscape genetics, and papers within the issue were commonly co-authored by collaborators among different disciplines. The distributed graduate seminar involved co-instructors from a number of different universities, as well as different disciplines (Wagner *et al.*, 2012). The goal of this seminar was interdisciplinary training of graduate students through face-to-face and virtual lectures, on-line interactions among students and instructors from remote locations, computer labs, group projects, and then finally a synthesis meeting among a group of students selected from the course as well as course faculty (Wagner *et al.*, 2012). These types of training models have been shown to be successful in helping to break down communication barriers through student immersion in collaborative projects (Reichman, 2004). Second, there have been a number of workshops and symposia associated with national meetings of different professional societies (e.g., Balkenhol *et al.*, 2009b). As we continue into the future, more and more students and postdoctoral researchers will be

trained through interdisciplinary courses, rotations among laboratories and other collaborative activities, thereby eventually making communication in landscape genetics seamless.

The Effects of Spatial Scale

The effects of spatial scale have been investigated in only a few landscape genetics studies, although consideration of multiple scales is important because focusing on one spatial scale may miss the influence of important landscape variables at a finer or broader spatial scale (Anderson *et al.*, 2010). The relative influence of independent variables at different spatial scales can be tested to establish the most appropriate spatial scale to include in a model (Cushman *et al.*, 2006; Murphy *et al.*, 2010). One study showed that different landscape variables influenced boreal toads (*B. boreas*) in Yellowstone National Park at different spatial scales (Murphy *et al.*, 2010). By testing the influence of landscape variables at multiple bandwidths (from 30 m to 960 m) connecting sites, it was shown that habitat permeability and topographic roughness influenced population connectivity at fine spatial scales, ridgelines were important at broad scales, and temperature and moisture had effects across a range of spatial scales (Murphy *et al.*, 2010). Another study showed the effects of spatial scale on genetic connectivity among pitcher plant midge (*Metriocnemus knabi*) populations (Rasic and Keyghobadi, 2012). Specifically, broad-scale landscape features that included bog size and the spatial arrangement and density of pitcher plants influenced fine scale female oviposition behavior, leading to both fine and broad scale patterns of genetic differentiation (Rasic and Keyghobadi, 2012).

These studies highlight the utility of investigations that span different spatial scales as the influence of landscape variables on gene flow at one scale may differ from those at another scale (Murphy *et al.*, 2010), or variables acting at one spatial scale may influence those at another scale (Rasic and Keyghobadi, 2012), possibly leading to incorrect inference about the truly important variables. In addition, studies of spatial scale can inform proposed management or development actions, for example, by simulation testing of the effect of different proposed road widths on species of conservation concern.

Spatial Replication and Multispecies Comparative Studies

Most landscape genetics studies focus specifically on one portion of a species' geographic range (Holderegger and Wagner, 2008; Segelbacher *et al.*, 2010; but see Short-Bull *et al.*, 2011). However, spatial replication is important, as landscape processes in one part of a species' range may affect gene flow differently than in another part of a species' range (Short-Bull *et al.*, 2011). An example is with the black bear, where different landscape variables affected genetic structure differently across the range (Short Bull *et al.*, 2011). For example, elevation was only important in areas that had standard deviations in elevation greater than 300 m (Short Bull *et al.*, 2010). In addition, landscape variables explained significantly more variation in gene flow among 11 out of 12 study areas for the black bear, but classical IBD explained gene flow in the twelfth. As a result, a study that only focused on the twelfth area by change would lead to the erroneous conclusion that landscape effects

were not important for gene flow among black bear populations, a logical conclusion for such a highly dispersing species (Short Bull *et al.*, 2010).

Variation in genetic structure could also be due to ecological differences among populations, such as varying interactions with the abiotic environment, species interactions, or sexual selection (Rundle and Nosil, 2005). The strawberry poison-dart frog represents an example, where genetic structuring appears to be correlated with sexual selection based on color pattern variation, rather than landscape features (Wang and Summers, 2010). However, differences in the relationships between gene flow and landscape features across a species' range could simply be due to variation in the landscape itself and not the biology of the species *per se* (Short-Bull *et al.*, 2011).

From an applied research perspective, lack of replication in landscape genetic studies can also impede the conservation of biological diversity. When genetic data are limited to a small portion of a geographic species' range, they may be incorrectly extrapolated to other portions of the range to guide management resulting in conservation measures that are ineffective (Short-Bull *et al.*, 2011; Waples and Gaggiotti, 2006). Thus, replicated landscape genetics studies can also contribute to a better understanding of the evolutionary ecology of a species, and consistency of the influence of landscape variables among regions lends more credibility to their general influence of dispersal and gene flow of a focal study species.

More multispecies comparative landscape genetics studies are also needed to understand whether features of particular landscapes have consistent or contrasting effects across study species. An example was a study of Columbia spotted frogs (*R. luteiventris*) and long-toed salamanders across an agricultural landscape (Goldberg and Waits, 2010). Urban and rural development were associated with the highest landscape resistances for both species, but the effects of specific habitat features differed. That is, a moisture gradient provided the least resistance for long-toed salamanders, but agriculture and shrub/clearcut habitat had the highest permeability values for Columbia spotted frogs (Goldberg and Waits, 2010). Another study that compared landscape genetic structure of three Pacific salmon species, showed similar genetic structuring at broad spatial scales, but at finer spatial scales, subbasin area affected genetic structure only in Chinook salmon (*Oncorhynchus tshawytscha*; Olsen *et al.*, 2011). Life history variation can also affect genetic structuring among closely related species in the same area. For example, bee-pollinated species of the plant *Penstemon* (*Penstemon deustus* and *Penstemon pachyphyllus*) had high genetic structuring and low gene flow relative to the hummingbird pollinated congener *Penstemon rostriflorus* (Kramer *et al.*, 2011). Thus, not only can multispecies studies suggest consistency of effects of some landscape variables, but they can also elucidate how ecological differences among related study organisms can translate to variation in effects of particular landscape features on genetic structure.

Moving Beyond F_{ST}

Although 19 different measurements of genetic distance have been used among landscape genetics studies, F_{ST} and its analogs (including G_{ST} , G_{ST}' , R_{ST}), were by far the most commonly used

(Storfer *et al.*, 2010). A variety of concerns have been raised regarding use of F_{ST} , including the fact that direct translation to the number of migrants per generation is often inaccurate (Whitlock and McCauley, 1999). That is, genetic analyses are considered indirect studies of dispersal; a distribution of allele frequencies among groups is used to infer species' dispersal patterns. Several authors have considered a number of problems with the assumption inherent in most landscape genetics studies – that spatial patterns of genotypic distributions reflect current dispersal patterns (Jaquière *et al.*, 2011; Marko and Hart, 2011). In general, however, F_{ST} -based metrics have equilibrium-based assumptions, and thereby a lag time may be necessary to detect changes in genetic structure that result from land use change (Landguth and Cushman, 2010). This is particularly disconcerting given the abundance of landscape genetics studies that are conducted in anthropogenically altered systems not expected to be in equilibrium. Empirical data support this concern, and studies actually showed that past landscape matrices explained patterns of genetic structure better than current patterns (e.g., Orsini *et al.*, 2008; Pavlacky *et al.*, 2009; Spear and Storfer, 2008). As such, researchers should consider use of other metrics that avoid equilibrium assumptions, such as D_{ps} (Bowcock *et al.*, 1994), or coalescent models that investigate allele genealogies (Marko and Hart, 2011).

Direct studies of animal movement have their own sets of problems, including limitations associated with techniques such as radio-tracking (e.g., cost and size of radiotrackers makes them unfeasible for relatively small study organisms) and mark-recapture studies, which tend to require large sample sizes and relatively high recapture rates (Jaquière *et al.*, 2011). In addition, inferring genetic structure from direct dispersal studies is tenuous inasmuch as animals that disperse from one habitat to another may not actually breed there due to a variety of reasons that include unfamiliarity with the new habitat, being socially ostracized, or stress associated with the migration event itself. One way of dealing with this issue is combining direct dispersal estimates with indirect genetic estimates, as has been done with studies that integrate habitat suitability modeling and landscape genetic analyses (e.g., Wang *et al.*, 2008).

The predominant use of pairwise distance-based analyses, such as genetic distance matrices and Bayesian assignment methods in landscape genetics relies on the implicit, and sometimes unrealistic assumption that the study species is clustered into groups. However, these methods may be inappropriate for organisms with uniform or non-clumped distributions, such as many plant species or high-dispersing animal species. Use of individual-based genetic distances (Manel *et al.*, 2007) or interpolation methods to create genetic surfaces among individuals (Murphy *et al.*, 2008) avoid assumptions of discrete clustering.

Landscape Genomics

Recent technological advances have led to the availability of vast amounts of molecular data available for landscape genetics studies, and researchers are now able to use large numbers of loci to assess the spatial distribution of adaptive genetic variation (Holderegger *et al.*, 2010; Manel *et al.*, 2010a;

Segelbacher *et al.*, 2010). Although the ability of natural selection to shape phenotypic differences among populations has long been recognized, we are now beginning to understand the molecular underpinnings of the spatial distribution of adaptive genetic variation. These studies not only benefit basic evolutionary biology, such as understanding species' range limits or ecological speciation, but it is also becoming increasingly important to assess the adaptive potential of natural populations in the face of global change (Manel *et al.*, 2010a).

Spatial analysis of genomic data in particular requires new analytical methods and approaches given the sheer size of the datasets (Manel *et al.*, 2010a; Segelbacher *et al.*, 2009). Indeed, the high statistical power to conduct tests of correlations of genetic variation and environmental variation using hundreds to thousands of loci is likely to result in a large number of spurious correlations, which may inflate numbers of candidate adaptive loci. Studies with hundreds to thousands of loci are useful for genomic mapping, as well as identifying candidate loci for adaptation to different environmental conditions (Holderegger and Wagner, 2008; Manel *et al.*, 2010a; Stinchcombe and Hoekstra, 2008). The latter approach has been termed "landscape genomics" (Joost *et al.*, 2007).

Four years after the term, "landscape genetics" was coined, Joost *et al.* (2007) developed a spatial analysis method (SAM) for testing the spatial correlation of large numbers of loci with environmental variables to reveal candidate loci for adaptation to environmental conditions. Similar to the advantage landscape genetics has relative to population genetics, SAM analyses add an explicit spatial component to "population genomics" studies, which depend on sampling large numbers of genetic markers dispersed throughout the genome. Population genomics studies reveal spatial patterns of genetic population structure that include "outlier loci", or those with differentiation that is greater than expected by the balance between genetic drift and migration (Luikart *et al.*, 2003). In turn, these loci are assumed to be under selection or physically linked to those under selection. As an example, an assessment of 392 AFLPs in the common frog (*R. temporaria*) among populations at varying altitudes in the Alps revealed eight candidate loci potentially involved in adaptation to altitude (Bonin *et al.*, 2006). Another study investigated whether hundreds of AFLP loci in the alpine plant, *Arabis alpina*, were correlated with environmental variables at both broad and fine spatial scales across an altitudinal gradient throughout Europe (Manel *et al.*, 2010b). Temperature and precipitation consistently influenced the distribution of alleles across all spatial scales, and 43% of the loci strongly correlated with environmental variables were consistent between fine and broad spatial scales. As such, several loci were also thought to be involved with adaptation to environmental variables that were thought to be site-specific (Manel *et al.*, 2010b).

It has been noted, however, that most landscape genomic studies are currently in the exploratory stage of identifying candidate loci (Manel *et al.*, 2010a, 2010b). That is, even hundreds of AFLP loci are not enough to pinpoint locations of candidate loci in the genome and thus, once a candidate locus is identified, a significant amount of downstream work is necessary to confirm its role in adaptation. Indeed, this work often includes fine-scale genetic mapping, along with assessing the fitness value of the genes themselves through

knockout experiments or other selection experiments (Hoffman and Willi, 2008; Manel *et al.*, 2010b). Even for organisms for which complete genome data and fine scale mapping exists (e.g., *Drosophila*, mouse), once loci are identified, the following experiments to confirm the adaptive value of candidate loci are still laborious. Although overcoming bioinformatic and experimental challenges is necessary to integrate genomic and spatial data in landscape genomics studies, it is an exciting time for evolutionary biologists, ecologists and population geneticists as we begin to truly unravel the genetic basis of adaptation.

This article is a revision of the previous edition article by Tamara L. Horton and Laura F. Landweber, volume 4, pp 415–426, © 2001, Elsevier Inc.

Glossary

DNA Deoxyribonucleic acid; a linear polymer of nucleotides that encode information for a cell.

Eukaryote An organism whose cell or cells have a membrane-bound nucleus.

Mitochondrion A eukaryotic cellular organelle that is used for cellular respiration and energy production.

Nucleus Compartment of a cell in which DNA is stored on chromosomes.

Protein A three-dimensional macromolecule constructed of amino acids that is formed based on an RNA sequence.

Protist A member of a diverse collection of eukaryotes that are defined only by their exclusion from other groups – plants, animals, and fungi.

RNA Ribonucleic acid; a linear polymer of nucleotides that is transcribed from DNA.

Introduction

DNA is often described as a blueprint for life, implying that knowledge of the primary sequence of nucleic acids in a genome can give biologists a complete picture of the organism built from these plans. However, neither life nor DNA is that simple. In reality, the sequence of nucleotides in a genome is often just a starting point for the construction of DNA genes and RNA transcripts, which undergo many alterations before organisms actually use the information to fashion their building materials.

Two fascinating modes of nucleic acid sequence modification are gene scrambling and RNA editing. Gene scrambling is the rearrangement of DNA segments between a transcriptionally active copy and an archived germline copy. Some genes are broken into more than 50 unordered fragments along a germline chromosome and then unshuffled during formation of an active somatic chromosome. Although gene unscrambling assembles existing DNA information into a new order, RNA editing of transcripts creates completely novel sequences that are not even found in the genome. Processing of edited RNAs alters the transcript length and nucleotide identity, and the transformations can render the expressed RNA form unrecognizably different from the DNA molecule of its origin. Although gene scrambling and RNA editing complicate our analysis of genomes, understanding the methods by which organisms achieve these genetic revisions gives us an appreciation for the diversity of ways by which nucleic acids can store and recombine information.

Gene Scrambling

Gene scrambling occurs when coding segments of DNA are mixed in a randomly or a nonrandomly shuffled order along a chromosome. Before the stored information can be expressed

by the organism, the pieces of the gene must be cut apart and reassembled in the proper sequential arrangement. These stunning acrobatics are performed in the genomes of spirotrichous ciliates, protists that have many unique and mysterious features. However, the fundamental lessons learned from spirotrichs about the flexibility of nucleic acid storage mechanisms are universally important.

Ciliates and Nuclear Dualism

Ciliates are unicellular protists that on phylogenetic trees diverge together with apicomplexan parasites and dinoflagellates, all members of the alveolates. The ciliates are a diverse monophyletic group, with certain species estimated to be as evolutionarily distant from one another as corn from rats. All ciliates share two features: a coating of cilia on their cell surfaces and two types of nuclei within single cells.

The two nuclei types in each ciliate cytoplasm are different sizes; they are called the *micronucleus* and the *macronucleus*. The tiny germline micronucleus is usually transcriptionally inert and functions solely in sexual exchange. In contrast, the large somatic macronucleus is responsible for gene expression, but its contents are only transmitted to asexual offspring. Ciliates reproduce asexually but are capable of exchanging genetic information in a sexual manner independent of reproduction. Conjugation between ciliates leads to an exchange of haploid micronuclei that fuse to form a zygotic nucleus (Figure 1). The biparentally created zygotic nuclei in each mating partner form new micronuclei and macronuclei, and the old macronuclei are destroyed.

DNA Processing during Macronuclear Formation

The micronuclear and macronuclear genomes do not have the same chromosomal structure. As the new macronucleus is

Figure 1 Ciliate sex. The micronuclei of conjugating ciliates undergo meiosis, exchange, and fusion to form new genetic combinations. Between steps 1 and 2, the ciliates conjugate. In the transition from step 2 to step 3, the micronuclei have undergone meiosis to form haploid micronuclei while the old macronuclei have been destroyed. In step 4, the haploid micronuclei are exchanged, and in step 5 they fuse. By step 6, two unique diploid micronuclei are formed with genetic material from both parents. At step 7, a new macronucleus is formed from each new micronucleus.

formed, diploid micronuclear chromosomes become polytene and reproducibly break at certain sites, portions of DNA undergo deletion, chromosomes are rejoined, and new chromosome ends are repaired by telomerase. DNA in the new, shortened chromosomes is differentially amplified so that copy numbers of individual chromosomes in *Tetrahymena thermophila* range from 45 to 9000. Spirotrichous ciliates tend to have higher copy numbers of chromosomes than the oligohymenophorans such as *Tetrahymena*, and these copy numbers are regulated by noncoding RNA (Nowacki *et al.*, 2010). Disparities in DNA copy number can relate to levels of gene expression, because the most highly amplified DNAs encode the highly expressed ribosomal RNAs, and the quantities of mRNA synthesis and cognate protein secretion from *Euplotes raikovi* pheromone genes directly correlate with the genes' individual macronuclear copy numbers.

Coding sequences in micronuclear genes are called MDSs for *macronuclear destined sequences* (or *segments*), whereas IESs are *internal eliminated* (or *excised*) sequences. MDSs and IESs are superficially analogous to exons and introns, respectively, although the latter two terms only refer to a particular type of RNA processing and do not apply to this unrelated restructuring of DNA. The amount of DNA eliminated during macronuclear formation varies extensively across diverse ciliates: the oligohymenophoran *T. thermophila* eliminates approximately 15% of its micronuclear genome, whereas spirotrichous ciliates such as *Stylonychia* and *Oxytricha* eliminate 95–98% of their micronuclear genomes to create macronuclear chromosomes that typically bear single genes and very little noncoding sequence (Prescott, 1994).

Scrambled Genes and the Unscrambling Process

The drastic genome rearrangements of spirotrichous ciliates are not confined to the extreme quantity of DNA deletions. The protein-coding MDSs in *Oxytricha* and *Stylonychia* species are sometimes disordered relative to their final position in the macronuclear copy. For example, Prescott and colleagues found that in *Oxytricha nova*, the micronuclear copy of three genes (actin I, α telomere-binding protein, and DNA polymerase α) must be reordered while intervening DNA sequences are removed in order to construct functional macronuclear genes. In *O. nova*'s micronuclear genome, the MDSs destined to construct the gene for α telomere end-binding protein (TEBP α) are arranged in the cryptic order 1–3–5–7–9–11–2–4–6–8–10–12–13–14 relative to their conventional order in the macronucleus of 1–2–3–4–5–6–7–8–9–10–11–12–13–14. Most impressively, the gene encoding DNA polymerase α (DNA pol α) in *Oxytricha trifallax* and *Stylonychia lemnae* is scrambled in 48 or more pieces in their germline nuclei (Figure 2).

Genome rearrangements in spirotrichous ciliates are guided by maternally inherited noncoding RNAs (Nowacki *et al.*, 2008) – the same noncoding RNAs that regulate chromosome copy number (Nowacki *et al.*, 2010). Homologous recombination at MDS boundaries is also part of the unscrambling process. A segment of DNA sequence at the junction between a particular MDS and its downstream IES usually matches the sequence at the junction of the next MDS and its upstream IES, leading to the correct ligation of the two MDSs over a distance. However, the presence of shared repeat regions as short as an average of 4 base pairs (bp) for non-scrambled MDSs and 9 bp for scrambled MDSs suggests that although these recombination guides may be necessary, they are certainly not sufficient to guide accurate assembly of the genes. Hence, it is more likely that the repeats satisfy a structural requirement for MDS joining rather than perform any role in substrate recognition, which the noncoding template RNAs provide instead. Otherwise, incorrectly spliced products of promiscuous recombination would dominate genomes since 2–4 bp repeats occur many thousands of times throughout the micronucleus. This incorrect hybridization could be a driving force in the production of newly scrambled patterns in evolution. Nonetheless, if this sort of ambiguous unscrambling actually occurs during macronuclear development, then only unscrambled molecules that contain both 5 and 3' telomere addition sequences are selectively retained in the macronucleus, ensuring that most haphazardly ordered genes would be lost.

The pattern of MDSs in the micronuclear genome provides a strong clue to both the ciliates' orchestration of the unscrambling process and the mutational events that led to the scrambling in each gene sequence. For example, in the previously mentioned gene encoding *O. nova*'s TEBP α protein, the micronuclear order of MDSs (1–3–5–7–9–1–2–4–6–8–10–12–13–14) predicts a spiral mechanism in the unscrambling path to link odd and even segments in order (Figure 3).

In contrast, the DNA polymerase α gene has at least 44 MDSs in *O. nova* and 50 in *O. trifallax* scrambled in a non-random order with an inversion in the middle; some MDSs

Figure 2 Overview of gene unscrambling. Dispersed coding MDSs 1–7 reassemble during macronuclear development to form the functional gene copy (top), complete with telomere addition to mark and protect both ends of the gene.

Figure 3 Spiral model for unscrambling in TEBP α .

are located at least several kilobases away from the main gene in an unmapped fragment. A hairpin structure could help resolve MDSs during unscrambling (Figure 4). Comparison of the *O. nova* sequence with that of *O. trifallax* allows precise predictions for the origin of new scrambled segments (Figures 4 and 5). Micronuclear junction sequences promote pairing between each MDS and the noncoding IES on the opposite side of a hairpin (Figure 4). Any mutation that leads to an increased stabilization of this hairpin during macronuclear chromosome formation would also increase the chance of

homologous recombination between correct segments within the micronuclear genome. Consequently, selection would favor the appearance of more scrambled MDS segments in such a nonrandomly scrambled gene since each additional MDS adds more paired junction sequences to stabilize the hairpin necessary for unscrambling the already existing MDSs. This explanation is consistent with the additional MDSs in the DNA pol α gene in *O. trifallax*. The arrangement of MDSs 2, 6, and 10 in *O. nova* could have given rise to the arrangement of eight new MDSs in *O. trifallax* (Figure 4) by multiple cross-overs in the germline micronucleus. Thus, the appearance of an inversion leads to the introduction of new MDSs in a nonrandomly scrambled pattern.

Gene scrambling in ciliates may have evolved as a product of an increased capacity for homologous recombination. The reason why it has been detected in only a restricted group of ciliates might reflect their increased levels of recombination, which generate both the scrambled arrangements and the subsequent process of unscrambling them. Although it is difficult to propose an adaptive argument for the presence and maintenance of such a complicated gene-decoding procedure, the forces that have led to ciliate nuclear dualism might be at the root of its origin. For example, Yao and Doerder independently proposed that the different roles required of the micronucleus and macronucleus, as well as intragenomic competition, may have led to disruptive selection acting on their genetic organization and chromatin structure. The accommodation of both types of nuclei within a single cytoplasm may promote or at least permit profound differences to arise that distinguish active genes from transmitted genes. Likewise, the gene scrambling present in certain spirotrichous ciliates may be a profound exaggeration of this solution to problems presented by ciliate life.

RNA Editing

RNA editing is the alteration of RNA sequences by base modifications, substitutions, insertions, and deletions (see Knoop, 2011

Figure 4 Model for scrambling of DNA pol α . Vertical lines indicate recombination junctions between scrambled MDSs guided by direct repeats. MDS 1 contains the start of the gene. MDS 10 in *O. nova* can also give rise to three new MDSs (13–15) in *O. trifallax*, one scrambled on the inverted strand, by two spontaneous intramolecular recombination events (x's) in the folded orientation shown. *Oxytricha nova* MDS 6 can give rise to *O. trifallax* MDSs 7–9 (MDS 8, shaded, is only 6 bp and was not identified in Hoffman and Prescott, 1997). *Oxytricha trifallax* nonscrambled MDSs 2 and 3 could be generated by the insertion of an IES in *O. nova* MDS 2 (similar to a model suggested by M. DuBois as cited in Hoffman and Prescott, 1997).

Figure 5 Proposed model for the origin of a scrambled gene. (Left) Birth of a scrambled gene from a nonscrambled gene by a double recombination with an IES or any noncoding DNA (new MDS order 1–3–2 with an inversion between MDSs 3 and 2). (Middle) Generation of a scrambled gene with a nonrandom MDS order from a nonscrambled gene with an inversion between two MDSs. (Right) Creation of new scrambled MDSs in a scrambled gene containing an inversion. Inversions may dramatically increase the production of scrambled MDSs by stabilizing the folded conformation that allows reciprocal recombination across the inversion.

for a comprehensive review). The process of rewriting RNA transcripts by editing produces major effects, even adding more than half of the nucleotides in some mitochondrial transcripts of kinetoplastid protozoa. In contrast, the impact of editing can still be large even in cases in which the physical extent of editing is small. For instance, in human apolipoprotein B transcripts, the replacement of a single cytidine (C) by uridine (U) results in the conversion of a glutamine codon to a stop codon; the early termination of apo B translation shortens the resultant polypeptide by half and removes a functional domain. Since the initial discovery of RNA editing as extensive U insertions and deletions in trypanosome mitochondrial mRNAs, many additional and apparently unrelated examples of editing have been found in organisms ranging from Ebola virus to humans. Substitution or modification editing exists in many nuclear and organellar RNAs among a diverse set of eukaryotes, whereas insertion or

deletion editing is found in a much more limited set of organisms (Table 1).

On first inspection, the use of RNA editing in gene expression seems inefficient. Why not encode genes in their final edited form rather than require an additional revision step? However, organisms exploit the ability to edit RNA in amazingly clever ways. RNA editing allows the persistence of deleterious mutations in DNA genomes: new point mutations and frameshifts may persist if they are repaired at the RNA level, and DNA copies of genes and control sequences in crowded genomes may overlap but generate two or more discrete RNA sequences through editing. RNA editing also offers an array of posttranscriptional modes of genetic regulation through the formation of start and stop codons, intron splice sites, and open reading frames and the potential alteration of microRNA (miRNA)–mRNA interactions, mRNA localization, and stability. Editing even permits

Abbreviations: mRNA, messenger RNA; tRNA, transfer RNA; rRNA, ribosomal RNA; ncRNA, non-coding RNA; mt, mitochondrial; cp, chloroplast.

Figure 6 Editing of a gene region by four overlapping gRNAs. Thick lines in the mRNA are encoded in the mitochondrial DNA. Thin shaded lines are inserted U's; the two asterisks are deleted U's (Reproduced from Maslov DA and Simpson L (1992) The polarity of editing within a multiple gRNA-mediated domain is due to formation of anchors for upstream gRNAs by downstream editing. *Cell* 70: 459–467.). Thin lines in the gRNAs are guide nucleotides (A or G) that pair with inserted U's. Vertical lines indicate Watson–Crick base pairs; colons indicate G:U wobble base pairs, illustrating formation of well-paired “anchors” between the 5' ends of gRNAs and the corresponding region of the mRNA.

single genes to produce multiple peptides, allowing combinatorial protein diversity.

The following sections review several models that explain our current understanding of the molecular and evolutionary basis of numerous forms of RNA editing.

Kinetoplastids: Cryptogenes to Proteins by U Insertion or Deletion

Kinetoplastids are a group of unicellular protists that include the pernicious trypanosome and leishmania parasites responsible for deadly human diseases such as African sleeping sickness and Chagas disease. Translation of mitochondrial mRNAs of kinetoplastids is impossible without massive RNA editing of the transcripts by insertion and deletion of uridine (reviewed in Aphasizhev and Aphasizheva, 2011). This editing drastically rewrites the coding regions of the transcripts by introducing and fixing frameshifts as well as creating stop and start codons. In some kinetoplastid mRNAs, editing creates more than 90% of the amino acid codons. Since the DNA copies of many genes are barely recognizable as sources of their cognate mRNAs, they have been named *cryptogenes*.

Although all kinetoplastids display specific, reproducible editing patterns in certain mitochondrial mRNAs, comparison of the editing patterns in a particular gene transcript across a variety of species reveals a trend in the extent of RNA editing within each species. The earlier diverging kinetoplastids exhibit more editing within the cytochrome c oxidase III transcript than their later diverging relatives. This implies that this type of RNA editing is ancient within this lineage and that its use has decreased over evolutionary time. However, the lack of U insertion or deletion editing in any other type of organism suggests that it arose specifically within the kinetoplastid lineage. Cavalier-Smith proposed that glycosomes, special organelles found only in kinetoplastids, may provide a clue to the origin of editing in these protists. Glycosomes permit an efficient anaerobic lifestyle, during which RNA editing may have become fixed by drift in the seldom-used mitochondria of the early kinetoplastids.

Guide RNAs (gRNAs) provide the specificity of the kinetoplastid editing mechanism (Blum *et al.*, 1990). They are small RNA transcripts that guide the editing machinery through base pairing with the mRNAs in edited regions. The gRNAs are complementary to small segments of the fully

edited mRNAs and thus serve as minitemplates to guide the addition and deletion of uridines from the preedited mRNA as they form a locally double-stranded RNA helix. An unpaired A or G in a gRNA signals for an editing event to insert a U into the mRNA. Complete editing of a mRNA often requires a set of many overlapping gRNAs. The affiliated set of overlapping gRNAs sequentially edit the mRNA from its 3' end to its 5' end. During editing, a complex of proteins called the *editosome* catalyzes the insertion and deletion of uridines until the length of each paired gRNA–mRNA region is maximized. The extent of G–U wobble pairs and conventional A–U and G–C pairs of each gRNA–mRNA pair directs the cascade of editing. Each subsequent gRNA binds the mRNA more stably than the last by possessing more Watson–Crick base pairs (A–U and G–C) in the anchor portion of the gRNA, leading to an overall 3'–5' directionality of editing (Figure 6).

Guide RNAs are encoded in the kinetoplastid mitochondrial genome. Kinetoplastids are named after the unusual structure of their mitochondrial genomes, which consist of a *kinetoplast*, a network of DNA inside a single, large mitochondrion located at the base of the flagellum. In one kinetoplastid subdivision, the trypanosomatids, the kinetoplast consists of a few identical maxicircles of 20–40 kb intertwined with thousands of heterogeneous minicircles of 0.5–3 kb. The maxicircles encode the mitochondrial genes and cryptogenes for respiratory proteins, ribosomal proteins, and rRNA. The only known role of the minicircles is to encode gRNAs. Bodonids, the other group of kinetoplastids, share the presence of a DNA network with the trypanosomatids but have a different structure for their minicircle homologs. In *Bodo caudatus*, the *minicircles* are noncatenated 1.4-kb circles. *Trypanoplasma borreli* has minicircle-like structures of 170 and 200 kb, with tandem 1-kb repeats encoding most gRNAs.

How did the gRNAs and minicircles come to exist as they do today? A product of mitochondrial DNA recombination provides a plausible explanation. Lunt and Hyman (1997) identified a minicircle of DNA excised from the major mitochondrial genome circle in a nematode. Similar intramolecular recombination within a kinetoplastid maxicircle might have led to the formation of minicircles encoding tiny portions of mRNAs whereas other unrecombined maxicircles still contained complete functional copies of the mRNA. If the minicircle copy of a gene fragment acquired a promoter that allowed transcription of an antisense RNA, then such a gene-encoding complementary RNA could have

given rise to a proto-gRNA. If the protein equipment responsible for catalyzing RNA insertions and deletions simultaneously arose or was recruited from another function to serve in RNA editing, then mutations in the mitochondrial mRNA could have been repaired by editing. Guide RNA-containing minicircles would be selectively retained in the genome, ensuring their survival.

Myxomycetes: Multiple Editing Types in Coding and Noncoding RNAs

Physarum polycephalum is a myxomycete, or plasmodial slime mold. It takes on many shapes and sizes throughout its life, morphing from microscopic amoeba to a multinucleate syncytium that can be several feet across and then forming millimeter-scale delicate, mushroom-like fruiting bodies. Mitochondrial transcripts for almost all messenger and structural RNAs in *Physarum* and related myxomycetes require several types of RNA editing to create functional products (reviewed in [Gott and Rhee, 2007](#)). Editing is extensive in *Physarum*; deep sequencing of total plasmodial mitochondrial RNA revealed 1333 sites of editing ([Bundschuh et al., 2011](#)). Most editing events involve the insertion of nonencoded nucleotides, with a total of 1347 nt added at 1324 sites. The vast majority are insertions of cytidine, but there are also a small number of specific and reproducible insertions of uridines, guanosines, an adenosine, and dinucleotides. The remaining editing sites involve three instances of A deletion, the replacement of the 5' nucleotide of two of the mitochondrially encoded tRNAs (see Mitochondrial tRNA Editing), and four sites of C to U changes. A unique feature of myxomycete editing is that they are the only organisms known to combine multiple types of editing within the same transcript. For example, *P. polycephalum*'s 1.5-kb transcript encoding cytochrome c oxidase subunit I (coI) undergoes 59 C insertions, a single U insertion, three dinucleotide insertions, and four sites of C→U base conversion ([Figure 7](#)). Insertion and base conversion editing have distinct evolutionary histories. The col gene of *Stemonitis flavogenita*, another myxomycete, shares all three types of insertional editing with *P. polycephalum* but lacks the C→U conversion editing in this transcript. Even the three

types of insertional editing did not all evolve simultaneously because U insertional editing is found in all myxomycetes to date, whereas C insertion and dinucleotide insertion are found only in some slime molds.

Studies in isolated mitochondria have demonstrated that multiple editing mechanisms are at work in *P. polycephalum* mitochondria. Nucleotide insertions occur cotranscriptionally, whereas C→U changes and 5' tRNA editing are posttranscriptional processes. Sites of nucleotide insertion are sprinkled throughout structural RNAs and in the coding regions of edited mRNAs but are never closer than nine nucleotides. Template regions required for editing fall within ~9 bp upstream of and downstream from nucleotide insertion sites, but no consensus sequences have been identified. Nucleotide insertion is remarkably accurate and efficient, with virtually all steady-state RNAs completely edited. Myxomycete insertional editing is clearly different from the posttranscriptional uridine insertion and deletion editing found in the kinetoplasts and, not surprisingly, no evidence for guide RNAs has been found by either deep sequencing or labeling studies. It is also mechanistically distinct from the cotranscriptional polymerase stuttering observed in paramyxoviruses (see Paramyxovirus and Ebola Virus: Polymerase Stutter Unites Reading Frames).

The sites of C→U editing in *P. polycephalum* are all in first or second codon position, similar to the case in plant organelle editing. Also similar is that the process of editing restores the conserved peptide sequence in this region so that the unedited *S. flavogenita* transcript codes for the same amino acids at these positions as does the edited *Physarum* transcript. In contrast, insertion sites are biased toward the third codon position, with roughly half of the added nucleotides found at this position.

Plant Organelles: C→U and U→C Editing Restores Conserved Amino Acids

Plant mitochondria employ rampant RNA editing, often involving hundreds of cytidine to uridine conversions (reviewed in [Takenaka et al., 2008](#); [Chateigner-Boutin and Small, 2010](#)). Plant chloroplast RNAs are also edited by C to U changes, but in higher plants these changes are much less frequent (see

Partial *P. polycephalum* mRNA sequence for gene encoding cytochrome c oxidase subunit I, with underlined text indicating inserted nucleotides and boxed text indicating C→U substitution events. Reproduced from [Gott JM, Visomirski LM, and Hunter JL \(1993\) Substitutional and insertional RNA editing of the cytochrome c oxidase subunit 1 mRNA of *Physarum polycephalum*. *Journal of Biological Chemistry* 268: 25483–25486.](#)

Stern *et al.*, 2010). A limited number of plant lineages also contain uridine to cytidine changes in chloroplast or mitochondrial RNAs. Although the mechanism for plant organellar editing is not fully understood, when cytidine triphosphate (CTP) residues of *in vitro* transcripts were labeled on their α -phosphate and on their cytosine base, the labels were retained after editing. This indicates that the C→U changes occur through a deamination of cytidine rather than a base or nucleotide substitution. *In vitro* and *in organello* experiments have shown that editing signals in plant mitochondria are largely local, with essential sequences falling within ~16–20 nt upstream and 0–6 nt downstream of the edited C. The involvement of pentatricopeptide repeat proteins (PPR) in plant organellar editing was first demonstrated by Kotera *et al.* (2005), who showed that editing of a specific site within the *Arabidopsis thaliana* chloroplast *ndhD* gene was dependent on the PPR protein CRR4. Since that time, many other members of the extensive PPR protein family have been linked to editing of specific editing sites in mitochondria or chloroplasts (reviewed in Fujii and Small, 2011). As of yet, however, no enzymatic activity has been demonstrated for these PPR proteins, leaving open the identity of the factor(s) involved in the deamination (or potentially transamination) and amination reactions.

RNA editing is present in both the mitochondrial and the chloroplast genomes of land plants, but it is absent in green algae and the liverwort *Marchantia polymorpha*. This distribution suggests that the plant editing systems share common components and may have arisen simultaneously in both organelles or have been transferred from one to the other. Plants that possess the ability to perform base conversion may exploit the conversions as a mechanism for repairing sequences disturbed by mutational drift. The observation that most of the edited sites in plant genes are in first or second codon positions supports this hypothesis because editing produces nonsynonymous changes in amino acids. Furthermore, Malek *et al.* (1996) found that the level of mitochondrial editing in plants correlates with G/C content. Indeed, Lu and associates (1998) determined that editing “reverses” all nonsynonymous U→C substitutions at the RNA level in *col* genes from eight gymnosperm species, eliminating almost all variation in the predicted protein sequences. Editing can regulate translation or enzyme activity; it creates stop and start codons and proteins of varying function. However, the pressure toward loss of editing appears to be greater than any selective advantage it confers since Shield and Wolfe’s (1997) comparison of edited sites over many plant species reveals a high rate of mutation of the genes toward the edited (uridine) nucleotide.

Mitochondrial tRNA Editing: Acceptor Stems and Anticodons

Mitochondrial genomes of some organisms seem pressed to economize space. “Junk” DNA is held to a minimum, and genes immediately abut their neighbors. Some tRNA genes overlap their 5′ and 3′ extremities. Base pairing of a tRNA’s 5′ and 3′ ends is essential to form an acceptor stem for aminoacylation. In mitochondria, incompletely paired tRNA acceptor stems are repaired by exchanging mismatched bases on one side of the acceptor stem for ones that complement those

bases present on the opposing stem (see Knoop, 2011). Thus, editing and the presence of an internal acceptor stem template allow the genome to repair mutations that may occur in response to selection for either nucleotide compositional bias or sequence compression.

In land snails, squids, and chickens, the overlapping ends of certain tRNAs disturb the crucial base pairing of the acceptor stems. RNA editing activity restores complementarity to these tRNAs by replacing mismatched 3′ guanosine, uridine, and cytidine nucleotides with adenosines, possibly by some form of polyA polymerase. In a platypus tRNA, there are three exchanged nucleotides (U→A, U→C, and A→C) in the 3′ half of the stem to complement the 5′ half of the acceptor stem, leading to the suggestion that this reaction might be carried out by a CCA-adding enzyme. The introduction of all four nucleotides in the 3′ portion of the acceptor stem is required for the maturation of mitochondrial tRNAs in the centipede *Lithobius forficatus* and the jakobid protist *Saculamonas euadoriensis*, suggesting a requirement for an RNA-dependent RNA polymerase in these cases. A different mechanism is required when nucleotides within the 5′ portion of the acceptor stem are replaced using the 3′ part of the acceptor stem as template. Initially described in the ameboid protist *Acanthamoeba* and the fungus *Spizellomyces*, this form of editing has also been found in the myxomycete *P. polycephalum* and is predicted to occur in many other species (Table 1). Editing of the *Acanthamoeba* and *Spizellomyces* tRNAs involves the removal of uridines, adenosines, and cytidines within the first three 5′ positions and replacement with purines complementary to a corresponding pyrimidine on the 3′ template side of the stem. This unusual 3′–5′ polymerization reaction is likely to be catalyzed by proteins related to Thg1, the enzyme responsible for the addition of a G₋₁ residue to the 5′ end of tRNA^{His}. Thg1-like proteins (or TLPs) from *Dictyostelium discoideum* have recently been shown to accurately repair truncated tRNA editing substrates (Abad *et al.*, 2011).

Mitochondrial tRNAs are also subject to A-to-I and C-to-U editing events (reviewed in Paris *et al.*, 2012). An extreme example of tRNA C to U editing is provided by the tRNA^{Pro} from the lycophyte *Isoetes engelmannii*, which differs from its mitochondrial template at 18 different sites (Grewe *et al.*, 2009). More commonly, editing changes the decoding properties of a tRNA by affecting the anticodon loop.

In opossums and other marsupials, the DNA encoding mitochondrial tRNA^{Asp} has the wrong anticodon. Although the rest of the tRNA has a canonical tRNA^{Asp} sequence, the anticodon, GCC, will pair with glycine codons rather than aspartic acid codons. About half of the tRNA^{Asp} transcripts are not edited and consequently are aminoacylated with glycine. The remainder are edited by a C→U change that restores the GUC aspartic acid anticodon. These are charged correctly with aspartic acid since this anticodon is used as a determinant of tRNA charging. Surprisingly, the standard tRNA^{Gly} (with a UCC anticodon) is present in the genome as well, and it could theoretically recognize all four GGN glycine codons by wobble. However, a mutation just outside of the anticodon region of this tRNA^{Gly} renders it incapable of recognizing the two glycine codons which the mutated tRNA^{Asp} can bind. A second example of anticodon editing occurs in trypanosomatid tRNA^{Trp}. In trypanosomes, all tRNAs are imported from the

cytoplasm. To decode the UGA codon as tryptophan in the mitochondria (but not the cytoplasm), a portion of the imported tRNA^{Trp} is edited within the anticodon, which results in a change from CCA to UCA.

Böerner and Pääbo (1996) suggest that marsupial mitochondrial editing became fixed through two mutational steps. First, a mutation occurred in the anticodon for tRNA^{Asp}, transforming it into a functional tRNA^{Gly}. Genomes with this mutation were still viable since the altered tRNA could regain its necessary function as tRNA^{Asp} through editing. A subsequent mutation in the original tRNA^{Gly} was not lost because of redundancy in tRNA^{Gly} activity: a mutation outside the anticodon of the original tRNA^{Gly} eventually left it unable to recognize the two glycine codons that the newly mutated tRNA^{Asp/Gly} could translate. After this second mutation in the original tRNA^{Gly}, back mutation of the tRNA^{Gly/Asp} anticodon (to form simply a tRNA^{Asp} anticodon) would be deleterious since the mutant tRNA^{Gly/Asp} serves double duty by pairing with both aspartic acid and glycine codons. Thus, RNA editing permitted a deleterious change in a genome and then became fixed when a second mutation made editing a requirement for expression of mitochondrial proteins.

Human Apo B and Beyond: Shorter Peptides and Regulatory Possibilities

Apolipoprotein B is present in two different forms in both humans and rodents. The long form, apo B100, is part of very-low-density lipoprotein particles that have a role in cholesterol metabolism, whereas the short form, apo B48, contributes to chylomicrons that transport dietary lipids. The two forms of the apo B protein are actually encoded by a single gene with mRNA that undergoes tissue-specific C→U RNA editing at nucleotide position 6666. The editing converts an encoded glutamine codon into a stop codon to create the short form of the peptide (reviewed in Blanc and Davidson, 2010).

Editing of the apoB mRNA requires both a cytidine deaminase and an auxiliary factor. The catalytic peptide is apo B RNA editing cytidine deaminase subunit 1 (APOBEC-1), whereas site recognition is conferred by an RNA-binding protein, ACF (APOBEC-1 complementing factor). Specificity of the cytidine deamination is determined by the primary sequence of the apo B RNA transcript, particularly an 11-base *mooring sequence*, located just five nucleotides downstream of the edited site. In addition to this required mooring sequence, three other *efficiency* elements are found in the 140-base region surrounding the edited cytidine. These upstream and downstream elements increase the effectiveness of the editing reaction.

Although the apoB transcript is the only known APOBEC-1 target within coding regions in normal cells, a recent transcriptome-wide comparison of intestinal mRNAs from wild type and apobec-1 deficient mice identified another 32 APOBEC-1 targets within 3' untranslated regions (3'UTRs). The majority of these new sites occur near sequence elements with significant homology to the apoB mooring sequence, making it likely that these C to U changes are catalyzed by the same enzymatic machinery (Rosenberg *et al.*, 2011). Although the functionality of these editing events has not been demonstrated as yet, most fall within conserved noncoding

regions, suggesting possible roles in message stabilization, translational efficiency, and localization.

Cytidine deamination may also play a role in human tumorigenesis. For example, an imperfect APOBEC-1 mooring sequence and efficiency elements are present within the coding region of the neurofibromatosis type I (NF1) tumor suppressor gene. Despite slight differences in position and sequence context, normal individuals exhibit very low levels of editing. In comparison, tumor tissues from NF1-affected individuals showed more than eight times the normal quantity of edited transcript. The NF1 gene encodes the neurofibromin protein, which is a putative homolog of yeast proteins in the ras signal transduction pathways. The proposed GTPase activating domain of the neurofibromin lies just downstream of the NF1 editing site, and indeed C→U RNA editing at the site transforms an arginine codon into a premature translation stop upstream of the domain. Thus, the editing of the NF1 transcript most likely cripples the tumor-suppressing activity of neurofibromin.

APOBEC-1 is part of a family of cytidine deaminases. The related activation-induced cytidine deaminase (AID) also works at the polynucleotide level, but its substrate is DNA rather than RNA. AID is involved in antibody diversification, playing roles in both somatic hypermutation (SHM) and class switch recombination (CSR) via the deamination of genomic cytidines to uridines. A third set of related proteins, the APOBEC3 subfamily, is involved in the suppression of retroelements and restriction of retroviral replication.

A→I Deamination: Multiple Peptides, Multiple Regulatory Possibilities

Deamination of another type alters additional RNA sequences in a range of metazoans. Removal of adenosine's amino group yields inosine, a nucleotide that the translation machinery reads as guanosine (reviewed in Nishikura, 2010). A number of the initially identified A→I transitions cause predicted amino acid changes, most frequently in neurotransmitter receptors and ion channels (reviewed in Pullirsch and Jantsch, 2010). Editing at most sites is not complete, resulting in the generation of multiple protein isoforms within the cell. Editing events within glutamate receptors, for example, adjust the calcium channel permeability and the speed of the desensitization response. Likewise, in the serotonin receptors, protein loops encoded by the edited region of the RNA interact with G proteins to turn on signaling pathways. The editing, along with alternative splicing, allows the exquisite fine-tuning of neural responses by increasing combinatorial protein diversity available from a single transcript. Posttranscriptional regulation demands the expenditure of less time and energy than transcription of multiple gene sequences.

More recently, transcriptome-wide and bioinformatics studies have revealed many thousands of additional sites of A to I editing in humans, nearly all within introns and 3' UTRs (e.g., Li *et al.*, 2009). The majority of these changes fall within repetitive elements (especially Alu elements) capable of generating long, partially double-stranded regions of RNA, a key feature of editing targets (see next paragraph). Possible functions of editing within these noncoding regions include alterations in miRNA-mRNA interactions (potentially altering

the level of translation), creation or elimination of splice sites, and changes in nuclear retention or stability.

A family of enzymes called ADARs (adenosine deaminase acting on RNA) is responsible for A→I editing activity. The largely double-stranded RNA regions required for ADAR action within coding regions are elegantly provided by pairing of the exonic sequences with intronic sequences in the pre-mRNAs. Neither mature mRNAs whose introns have been removed by splicing nor pre-mRNAs with mutations disturbing intron–exon complementarity act as substrates for editing in transfected cell lines. Mice genetically disabled for A→I editing at a single site demonstrate the importance of RNA editing in glutamate receptors. Brusa *et al.* (1995) removed an intron region crucial for creating a double-stranded editing substrate from the mouse GluR-B gene. Heterozygotes for this editing-disabled allele displayed severe epileptic seizures and premature death within 3 weeks of birth. The decrease in edited mRNA levels led to a fivefold increase in the calcium flow into their neurons and serious damage to their nervous systems.

At least three different ADAR enzymes are expressed differentially in human tissues, and they display discrete editing abilities at various mRNA sites *in vitro*. Mice engineered to lack ADAR2 demonstrate a phenotype similar to the GluR-B intron deletion described previously, but these mice can be “rescued” by the introduction of a GluR-B gene that is edited at the Q/R site, indicating that this target is acted on by ADAR2. ADAR3 knockout mice appear normal, but ADAR1 deficient mice are not viable, displaying widespread apoptosis and defects in hematopoiesis.

Scott (1995) suggested that ADARs might have evolved for an antiviral function, destabilizing RNA genomes by modification and subsequent unwinding. Interestingly, a devious viral genome coopted this function and uses host adenosine deaminases to its own benefit. Hepatitis delta virus (HDV), a single-stranded RNA subvirus of hepatitis B, has only one known gene product, the delta antigen. The short form of delta antigen stimulates replication of the genome, whereas the long form of the antigen suppresses replication and is necessary for packaging HDV. The short and long forms of the delta antigen differ only by a single A→I base change of the negative strand, or antigenome. The base conversion replaces a stop codon at the end of the shorter peptide’s mRNA with a tryptophan codon to allow read through of the longer peptide. *In vitro*, ADAR1 is capable of inducing this A→I change on the antigenome of the HDV virus, suggesting that either this or a related enzyme edits HDV *in vivo*. In exquisite control of the reaction, the long-form delta antigen acts as a repressor of editing in a negative feedback loop. The repression prevents accumulation of unduly high levels of long-edited antigen, which would lower the level of viral replication.

Paramyxoviruses and Ebola Virus: Polymerase Stutter Unites Reading Frames

Two other types of viruses also capitalize on RNA editing processes as a method of increasing information storage while under pressure for genome size constraint. The RNA genomes of the paramyxoviruses have several overlapping genes. Some

of these genes are activated for expression by ribosomal choice, whereas others become available by cotranscriptional RNA editing. The polymerase may slip as it travels through a purine run, adding from one to six extra guanines, depending on the sequence present in the particular virus species. The stuttering polymerase thereby fuses coding regions together to make extended versions of genes.

Many viruses use an apparently similar mechanism to add poly A tails to mRNA transcripts. When the RNA polymerase reaches the U-rich regions, it adds additional nontemplated adenines to create the tails. In paramyxoviruses, RNA editing activity may be related to a process that corrects genome length, maintaining length in multiples of six nucleotides. The substrate for the RNA polymerase is the RNA genome complexed with the capsid in hexamer-length segments. Hausmann and colleagues (1996) note that if the genome length is not a multiple of six, then the polymerase inserts or deletes guanines or adenines from the same region in which the RNA editing occurs.

Another RNA virus, the infamous Ebola virus, uses a comparable mechanism to insert adenines into a sequence to unite two reading frames. In this case, the sequence of the site where adenine addition occurs appears similar to viral poly A addition sites. In contrast to the paramyxovirus editing, the additions occur even when the RNA is produced by a non-native polymerase and thus must be intrinsic to the template sequence or structure. T7 transcription of the Ebola mRNA *in vitro* results in edited product, although in a lower quantity than when transcribed by Ebola’s RNA polymerase.

Thus, once considered a molecular anomaly unique to protists, RNA editing is now recognized as a vital part of gene expression in a wide distribution of eukaryotes and their viruses. Organisms can alter RNA sequences through many different mechanisms by recruiting enzymes such as deaminases, nucleases, ligases, and special polymerases to specific RNA editing tasks. Editing clearly arose multiple times in evolutionary history in the various forms of both insertional and substitutional editing, all of which profoundly affect the expression of RNAs, the products they form, and the biological processes in which they participate. RNA editing is significant in cancers, cholesterol regulation, and neural function in vertebrates as well as in the *de novo* creation of coding sequences from obscured mitochondrial genes.

Furthermore, the impact of editing on the genomes that employ it is astounding. Genomes that use editing may become increasingly lenient toward persistence of deleterious mutations. Large amounts of genetic information and control devices may be confined to small spaces. Lastly, RNA editing, like gene scrambling, establishes a device for generating combinatorial sequence diversity.

Glossary

Allele (originally **allelomorph**) A form of variant (sometimes called a mutation) of a gene.

Diploid Individual who has two sets of chromosomes, usually received from different parents, in contrast to a **haploid** organism such as most microorganisms, the gametophyte stage of higher plants and some parthenogenetic forms (e.g., male ants and honeybees). It may have the same form or allele of a gene on both members of a chromosome pair (in which case it is homozygous) in different forms (alleles) (in which case it is heterozygous).

Gene Historically, the inherited factor which determines a trait. Tends to be used somewhat loosely; more strictly represents a place or locus on the chromosomes which codes for a particular function.

Gene (strictly allele) frequency The frequency of an allele in a population.

Genome The total genetic composition of an individual.

Genotype The allelic composition of an individual at a particular locus.

Mutation Change in an allele, producing a different allele; rate of occurrence affected both physically (especially by ionizing radiation) and by many chemicals. It may also refer to changes in a chromosome (involving duplication, deletion, or inversion of a segment).

Phenetics The study of phenotypes, usually describing the grouping of organisms into taxa on the basis of estimates of similarity.

Phenotype The appearance (function or behavior) of an organism.

Background

Phenotypes are the appearance and properties of real animals and plants—living and dying, reproducing and bearing fruit, and succeeding or failing—but in themselves they are the products of interactions between the inherited (genetic) material and the environment, both before and after birth. The distinction between genotype and phenotype is one of the more important ones in biology: A phenotype may be produced by several different genotypes, whereas a genotype may manifest as several different phenotypes, particularly when reacting with different environments.

The distinction between inherited constitution and external appearance (i.e., between genotype and phenotype) was one of the most important demonstrations of Gregor Mendel (1822–1884) in his series of breeding experiments with peas which laid the foundation for genetics, and in which he recognized that a character may be inherited in a dominant or a recessive manner. An organism manifesting a dominantly inherited trait (in Mendel's case, round as opposed to wrinkled pods or colored as opposed to white flowers; more familiar examples are brown versus blue eyes in humans or brown coat color versus albino in rabbits or mice) may carry both alleles

for the dominant trait or one for the dominant and one for the recessive trait. That is, it will have the same phenotype but could be genetically homozygous or heterozygous. A distinction between genes and their manifestation was also implicit in August Weismann's (1834–1914) embryological division between germplasm (which gives rise to reproductive cells) and soma (or body). However, the formal nomenclature phenotype and genotype was devised by the Danish botanist Wilhelm Johannsen (1857–1927), who introduced the word gene for the material basis of an inherited character, and thence the terms genotype and phenotype.

Johannsen set out to investigate the relationship between (phenotypic) variation and selection. The rediscovery of Mendel's work in 1900 led to a rift between the biometricians [notably Karl Pearson (1857–1936) and W. F. R. Weldon (1860–1906)], who followed Darwin (1809–1882) in viewing small continuous variation as the raw material of evolution, and the “mendelists” (or geneticists) [led by William Bateson, (1861–1926)], who believed that large discontinuous saltations (or mutations) were the main cause of variation. The problem was the maintenance of continuous variation. Darwin had postulated a continuous replenishment of variation in order for selection to act, but he did not know its source. His

proposal of “pangenesis” was an effort to solve the problem. Weismann’s demonstration of the early separation in development of the reproductive tissue from the rest of the body supported the general assumption at the time that continuous variation was produced by environmental effects. Intraspecific variation (i.e., subspecies or local races) was therefore regarded as environmentally caused; the species was viewed as monotypic in a way that had much in common with the pre-Darwinian ideal or Linnean type.

Johannsen experimented with a self-fertilized cultivar of the bean *Phaseolus vulgaris*. The implication of this was that all the descendants of a single individual would have the same genes and constitute what Johannsen called a “pure line.” Although individual beans might be different (due, for example, to their place in the pod), the mean and variance of all the characters of plants in a pure line were the same and were not affected by attempts at selection, i.e., plants grown from both small beans and large beans produced beans of the same average weight as that of all the plants in the pure line. In contrast, plants grown from crosses between pure lines had different (usually intermediate) characteristics from the parents, although these characteristics remained constant in pure lines derived from each cross. Johannsen argued that selection on continuous variation was inevitably ineffective, and the only variation on which selection could work depended on new mutation. This strengthened the contemporary assumption that evolution was bound up with mutations and their rate of occurrence, and that individuals were largely genetically uniform (i.e., homozygous at most loci for “wild-type” alleles).

This assumption became built into conventional population genetic theory so that when recessive traits manifested in inbred populations (usually in the laboratory or garden, but occasionally appearing under wild conditions) they were assumed to be recent mutations in the process of elimination by natural selection. Most mutations seemed to be deleterious to their carriers (which would be expected if they were random changes in a functioning organism), which meant that high mutation rates would inevitably impose a burden on a population. In 1950, at a time of acute concern about the genetic effects of atomic warfare, H. J. Müller (1890–1967) proposed the concept of “genetic load” and showed that a doubling of the mutation rate in a slow-reproducing species such as humankind could lead to extinction through genetically caused death.

The work of Bateson, Johannsen, and other early geneticists (one of the most influential was the Dutchman Hugo de Vries, 1848–1935) led to the isolation of genetics from evolutionary studies, particularly as represented by paleontology. This was resolved by the theoretical work of Sewall Wright (1889–1988), J. B. S. Haldane (1892–1964), and especially R. A. Fisher (1890–1962). Fisher published significant papers in 1918 and 1922 describing the expected biometrical properties of a Mendelian (i.e., breeding) population and the effects of an allele substitution on a quantitative (i.e., continually varying) character. (The papers were published by the Royal Society of Edinburgh; the first one was rejected by the Royal Society of London on the advice of Karl Pearson and the geneticist R. C. Punnett.) He went on to argue that dominance (and recessivity) are traits that have evolved and

this explains why the majority of new mutations are recessive, detrimental, and have a major effect (i.e., on the phenotype); most of the data available at the time were from laboratory breeding of *Drosophila melanogaster*. Fisher reasoned that there was no intrinsic reason for a mutation occurring for the first time to be either dominant or recessive; the greatest probability is that it will be intermediate, with an effect somewhere between its expression in double dose (i.e., when homozygous) and the unmodified condition. However,

1. Mutations occur repeatedly at virtually every locus. The rare (approximately 1 in 10^{-5}) mutational events we observe are recurrences of something that has happened thousands of times in the past.
2. When a mutation occurs, it will almost always be present in the heterozygous condition: If an allele has become relatively common in a population so that a fresh mutation to it has a reasonable chance of occurring in an existing heterozygote, then mutation cannot be the only force influencing its frequency.
3. If a newly arisen allele has a beneficial effect on its carrier, combinations of it with other alleles that increase its effect will have a higher fitness than any which decrease it. This will repeatedly occur so that the architecture of the species will become modified to the extent that any new occurrences of that advantageous allele will always produce the maximum effect in its carrier; this will almost always be in the heterozygous condition. In other words, beneficial characters will be selected for dominance and will also spread to replace the previous expression of the trait. Conversely, alleles which are deleterious in the heterozygote are only likely to be transmitted in combinations in which their effect is least, i.e., there will be selection for a small heterozygous effect (in the direction of recessivity).

Fisher put forward these ideas from first principles. They were received skeptically because of the difficulty in believing that selection pressures would be strong enough to allow genes which modify dominance to spread. In pre-1950 days primary selection coefficients were thought to be approximately 0.1 to 1.0% and second-order effects were believed to be much less. Haldane suggested that dominance was more likely to be the effect of alleles with a biochemical or developmental margin of safety becoming the normal allele. Since they could exercise undiminished action when heterozygous, mutant alleles would be recessive and deleterious. However, Fisher’s theory has been proven to be correct on many occasions, and although it may not apply for every allele at every locus it has considerable historical significance in bringing together paleontologists and geneticists, and it has relevance in highlighting an important factor influencing genetical architecture.

Fisher was the first to demonstrate the experimental modification of dominance by crossing domestic poultry with wild jungle fowl for five generations. This changed the inheritance of certain characters so that a degree of heterozygous manifestation occurred where complete dominance had previously prevailed. Fisher suggested that the dominance of the traits he studied had been attained during domestication as a result of selection for the more striking heterozygotes.

A more complete demonstration of the influences of modifying genes on dominance was performed by E. B. Ford (1901–1985) by breeding from the greatest and least expressions of a variable yellow variant (*lutea*) of the Currant Moth (*Abraxas grossulariata*). Although the difference between *lutea* and non-*lutea* can be regarded as caused by a single allelic difference, after only three generations of selection Ford produced heterozygotes virtually indistinguishable from the *lutea* homozygote in selection for the yellowest individuals and ones most like the typical homozygote in the white selection line. In other words, he had changed the heterozygote from a position of no (or intermediate) dominance to complete dominance or recessivity respectively. Ford then crossed his modified heterozygotes with unselected stock, and by the second generation (when the selected modifiers would have a chance of segregating independently) the original variable heterozygotes reappeared: He thus showed that it was the response of the organism rather than the gene that had changed.

Laboratory experiments of this nature have been carried out on a variety of organisms and a range of characters. An experiment particularly informative with regard to genetical architecture in the wild was carried out by H. B. D. Kettlewell (1907–1979) using British and Canadian peppered moths (*Biston betularia* and *Amphidasydes cognataria*, respectively; these are fully interfertile). Although there is a melanic form (*swettaria*) in the North American species, it is comparatively restricted in its distribution, and only pale (or typical) moths occur over vast tracts of Canada.

When a melanic heterozygote and a typical homozygote of British origin are mated, the offspring are clearly dark or light: The melanic character is a straightforward dominant. Even when the typical moths come from Cornwall in extreme southwest England where melanics have never been reported, only a slight loss of complete dominance occurs and that only after several generations of crossing melanics back to Cornish stock (i.e., back-crossing a melanic from several generations of melanic $\times$ Cornish cross with a “pure” Cornish parent). This modification consists of some white dots on the normally jet-black wings of the heterozygote. Perhaps significantly, this slight heterozygous expression of the gene gives specimens similar to those caught in the early days of the spread of peppered moth melanism in the mid-nineteenth century and which are now prized collectors’ specimens. This white speckling has long since disappeared in wild-caught British specimens, and modern heterozygotes are indistinguishable from melanic homozygotes. Melanism has become fully dominant during the ensuing decades.

However, there has been no opportunity for dominance to evolve in Canadian peppered moths. When British melanics are crossed to Canadian stock (from areas where *swettaria* does not occur) the first-generation progeny segregate as dark or light in the same way as in a cross between British moths. In the first generation, the dominance modifiers in the British parent will be carried on the chromosomes in the same order as in British stock and produce dominance in the same way. In the next generation, the gametes contain chromosomes which have crossed over between the British and Canadian grandparents. Consequently, in the second generation, the “switch” between pale and black forms does not operate as efficiently. Kettlewell crossed heterozygotes from a British $\times$ Canadian

mating with Canadian moths and repeated this back-crossing for four consecutive generations, after which the heterozygotes ranged from black to pale—there was no sign of dominance. He then reversed the procedure and mated his “broken-down” melanics to British typicals. The dominance of the condition was immediately reestablished: The architecture of the British chromosomes shaped a clear segregation between a dark heterozygote and a pale homozygote.

Fisher’s theory has proved correct in many similar experiments in both plants and animals, and although it may not be universally operative it provided the genetical basis for the understanding between disciplines that was needed before the neo-Darwinian synthesis could occur.

As late as 1932, T. H. Morgan was asserting that “natural selection does not play the role of a creative principle in evolution,” but 10 years later all but a very few biologists were agreed on an evolutionary theory based firmly on Darwin’s ideas knitted with subsequent developments in genetics. This coming together was described by Julian Huxley as the “modern synthesis” in a book with the same name published in 1942. The synthesis can first be seen in three English books: R. A. Fisher’s *Genetical Theory of Natural Selection* (1930), E. B. Ford’s *Mendelism and Evolution* (1931), and J. B. S. Haldane’s *Causes of Evolution* (1932). It was consolidated in three works from America: Theodosius Dobzhansky’s *Genetics and the Origin of Species* (1937), Ernst Mayr’s *Systematics and the Origin of Species* (1942), and George Gaylord Simpson’s *Tempo and Mode in Evolution* (1944). As Mayr noted, it did not occur as a result of one side being proved right and the others wrong but rather from “an exchange of the most viable components of the previously competing research traditions.”

The Making of a Phenotype

In the simplest microbial systems, there is a one to one relationship between gene action and phenotype: Change in a gene is likely to produce a change in its product, which will manifest directly in the organism as an altered character, perhaps the loss or modification of an enzyme. Such simple relationships exist in all organisms, however complex. There are more than 200 “inborn errors of metabolism” in humans, each resulting from changes in a particular gene, producing a change of phenotype in the whole organism. For example, albinism is due to the inability to synthesize melanin, which is made from tyrosine under the influence of tyrosinase, which is under the control of a gene on chromosome 11 in humans¹; “classical” hemophilia results from the absence of a protein (factor VIII) coded by a gene on the X chromosome. However, most traits are affected by many genes. For example, blood clotting in mammals is effected by a cascade of physiological reactions, each under the control of a different gene(s). Efficient clotting requires all the different stages to be operating, and defects in any stage (especially the genes directing the relevant proteins and enzymes)

¹In fact, human albinism can be due to genes on at least two different chromosomes. There are also mutations at another locus on chromosome 11 which cause albinism, but in this case the tyrosinase enzyme is apparently normal. Both genes produce an albino phenotype, but the phenotypes can be distinguished clinically.

will lead to a “bleeding” phenotype. In blood clotting it is possible to detect where the error lies because we know the normal determinants of clotting in detail. For most traits we do not have information about the steps in their formation. One of the benefits of genome mapping is that the genetical determinants of complex characters will be analyzable in an orderly way. Currently, most phenotypic analysis is biometric rather than genetic.

For example, the tails of house mice may be shortened by mutations at approximately 40 loci. We know the action of many of these genes: Some affect the notochord, some cell division rates, and some inductive relations between endoderm and mesoderm. We also know that the tail length of mice varies between different inbred strains of mice (which are similar in the genetic sense to Johannsen’s pure lines) and that we can increase or decrease tail length by selecting wild-caught animals or the products of crosses between inbred strains. We do not know which genes are variable (or segregating) in any one population or which genes are being affected by selection. However, it is clear from many selection experiments that the genes affecting any complex trait are distributed throughout the genome (i.e., over many chromosomes) and that selection for any one trait may “unbalance” the genome.

The concept of genomic balance (often called genomic or genetic architecture) is important. When a normal outbreeding species, such as maize, sugar beet, poultry, or *Drosophila*, is made to inbreed by manipulating its breeding system, the individuals characteristically decline in vigor and fertility until they stabilize at a stage before complete homozygosis is approached. The amount of this inbreeding depression varies from one line to another within any species. When two inbred lines are intercrossed, the F_1 (i.e., the first-generation progeny) show a considerable increase in vigor and fertility, known as hybrid vigor or heterosis. In general, the F_1 phenotype is similar to that in the population from which the inbred strains were derived. If F_2 ’s are raised and inbreeding is resumed, inbreeding depression will again occur, although not necessarily to the same extent as in the original lines. Inbreeding depression is often reflected in increased variability not only between individuals but also among repetitive parts such as bilateral characters in animals and floral morphology in plants; fluctuating asymmetry, in which there are differences between the right and left sides of individuals, is commonly used as a rough indicator of inbreeding. F_1 ’s tend to show decreased variability. Michael Lerner argued that this indicates an innate superiority of heterozygotes over homozygotes, perhaps because of a greater biochemical flexibility in the former. It is a phenomenon which has produced considerable research interest, particularly among marine biologists. Lerner argued that if artificial selection is suspended before much of the variation has been lost (as homozygosity increases) natural selection will tend to restore the character (and hence its genetic determinants) to an equilibrium value, with the mean of the character which was artificially selected tending to revert toward its original value; he called this genetic homeostasis.

Artificial selection tends to accumulate alleles which act on a character in a particular way, e.g., to increase its size or the number of elements making up a repeated trait. If we make the reasonable assumption that any population needs to combine phenotypic uniformity in a stable environment with

long-term flexibility should the environment change, the easiest way to do this is for the character in question to be controlled by alleles at different loci, with some alleles acting to increase the expression of the character and others acting to decrease it. In such a case, Fisher showed that selection will favor linkage between the loci responsible, with the evolution of “balanced” chromosomes containing “positive” and “negative” alleles. The simplest situation will involve two segregating loci, A,a and B,b with A,B acting in one direction and a,b in the other (i.e., additive genes). The intermediate type can be either the attraction or the repulsion heterozygote, AB/ab or Ab/aB. However, the latter will be favored since it will be less likely to produce zygotes giving the extreme phenotypes (Figure 1). For the same reason, any mechanisms bringing about closer linkage between the loci concerned (such as a chromosomal inversion) will be favored.

This theoretical arrangement has been subjected to experimental analysis, mainly through selection experiments in *Drosophila*, and has been generally confirmed; it receives support from the distribution of “quantitative trait loci” identified by molecular techniques. It also accounts for other properties:

1. Selection (natural or artificial) for any character almost invariably produces correlated responses in additional developmentally independent traits of the phenotype.
2. Gene loci affecting viability traits are interspersed along the chromosomes with loci affecting other characters.
3. The highest rate of artificially induced new variation by mutation is many times less than that occurring spontaneously through recombination.
4. There is widespread occurrence of chromosomal inversions in nature.
5. Deleterious gene combinations (even to the point of lethality) may occur solely as a result of recombination.

There are a few cases in which the different genes contributing to complex variation have been identified. This has been done for the determinants of the pin thrum polymorphism in *Primula vulgaris*, in which different members of a linked group of loci control anther height, style length, pollen size, rate of pollen tube growth, and length of the papillae on the stigma; for mimetic patterns in the African swallowtail butterfly *Papilio dardanus*; and for color and banding patterns in the land snail *Cepaea nemoralis*. In house mice, approximately 16% of genes with an identified function are concerned with behavior and have been located on 19 of the 20 chromosomes of the species. However, in most cases it is only possible to conclude that different components of a character complex are inherited as a unit, i.e., that the gene complex is coadapted.

Coadaptation is presumably the reason why the genomes of interfertile species do not always merge when they meet. For example, races of dark- and light-bellied house mice (referred to as *Mus musculus domesticus* and *M. m. musculus*, respectively, although they should perhaps be given full species status) meet in a narrow zone of intergradation across Jutland (Denmark) and south through Germany. Although the two forms readily interbreed in the laboratory, the hybrid zone has apparently been constant for at least 50 years. Gene frequencies on the two sides of the hybrid zone are very different. Remarkably, the frequencies in the light-bellied form in California, which are descended from the same stock as the light-bellied Danish

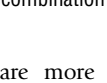

Parents		Offspring					
Chromosomes	Phenotypic score	From non-recombinant gametes		With recombination in one parent		With recombination in both parents	
		Chromosomes	Phenotypic score	Chromosomes	Phenotypic score	Chromosomes	Phenotypic score
Repulsion							
	2	Ab / aB	2	AB / aB	3	AB / ab	2
	2	Ab / Ab	2	AB / Ab	3	AB / AB	4
	2	aB / aB	2	ab / aB	1	ab / ab	0
	2	aB / Ab	2	ab / Ab	1	AB / ab	2
Attraction							
		AB / ab	2	AB / Ab	3	Ab / Ab	2
		AB / AB	4	AB / aB	3	Ab / aB	2
		ab / ab	0	ab / Ab	1	aB / Ab	2
		ab / AB	2	ab / aB	1	aB / aB	2

Figure 1 Effect of linkage on the incidence of the extremes of manifestation of an additively inherited character. If A,B produce a phenotype effect of 1 and a,b an effect of 0, the matings between two repulsion heterozygotes are least likely to produce extreme phenotypes (they will only appear if recombination between the two loci occurs in both parents).

animals, are more like those in the light-bellied Danish population than are the light-bellied Danish ones from their dark-bellied neighbors. A similar situation exists in deer mice (*Peromyscus polionotus*) in Florida and also in carrion and hooded crows in the same area in which the dark- and light-bellied mice occur in Europe. However, some species lose their identity wholly when brought into breeding contact. This has happened commonly in New Zealand, where much of the terrestrial biota has been introduced. Hybrid zones are common. Presumably these occur when coadaptation has not evolved.

Formal Analysis

In the past, it was suggested that the genes which control major or qualitative traits are different from those which affect quantitative ones (oligogenes and polygenes, respectively). This distinction is now rarely made. In other words, it is assumed that genes affecting quantitative traits (such as weight or size or physiological properties such as metabolic rate) follow Mendelian patterns of inheritance, may have multiple alleles, can mutate, change in gene frequency, show dominance, etc. Quantitative inheritance is merely a general case of the interaction of genes in which the interacting components are little or wholly known.

The number of genes which affect a trait can be estimated by the amount and speed of response in a selection experiment or by the mean and variance of the character as measured in a population. Using these techniques it has been calculated that human skin color may be determined by only 5 or 6 loci,

whereas the number of genes affecting oil and protein production in maize may be as high as 54 and 122, respectively. However, such estimates are very dependent on the nature of interactions between the loci concerned and should be regarded as no more than suggestive of a large or small number.

The simplest assumption in multigenic trait determination is that all the loci affect the trait equally and therefore additively. However, detailed analysis has shown that in many (perhaps most) cases, a few genes have a major effect and many genes have a minor effect. For example, in the well-studied case of variation in sternopleural bristle number in *D. melanogaster*, approximately 10 loci account for 75% of the genetic variation in number. The situation is further complicated by pleiotropy: A gene may have a major effect on one character but minor effects on others. For example, phenylketonuria is an inborn error of metabolism producing severe mental retardation in humans and is produced by the nonfunctioning of phenylalanine hydroxylase, which is controlled as a recessive trait by a single gene on chromosome 12. The same enzyme is involved in melanin synthesis, and phenylketonurics have slightly paler hair and complexion than their normal sibs. The gene can therefore be regarded as having a major effect on intelligence but a minor effect on pigmentation.

However, a quantitatively inherited trait will be more likely than a qualitative one to be affected by environment. A group of individuals having identical genes for growth (i.e., a pure line or a clone) may show considerable variation in size due to differences in available nutrients. Although the same potential for size is present in the initial gene products, the manifestation of the phenotype will be limited by such factors as food availability.

Conversely, a population of genetically heterogeneous individuals may grow to the same size if no gene–environment interaction is limiting (or if different interactions compensate for each other). Generalizing, we can express the phenotypic value P for individual i in environment j as

$$P_{ij} = G_i + E_j$$

where G_i is the genetic contribution of the i th genotype and E_j is the environmental deviation resulting from the j th environment.

A particular genotype may do well in a particular environment, implying a specific interaction between the two. In this case,

$$P_{ij} = G_i + E_j + GE_{ij}$$

In practice, there will be variance of these components so that

$$V_p = V_G + V_E + 2\text{Cov}_{GE}$$

where V_p , V_G , V_E , and 2Cov_{GE} are the phenotypic, genetic, and environmental variance and the genotype–environment covariance, respectively. The genotype–environment covariance is positive when genotypes with higher values are in better environments and poorer genotypes have poorer environments. This may occur in animals when one member of a litter is large because of its genes and gets more food from its parents or when an animal is socially dominant for genetic reasons and therefore has more resources in food and spaces. A plant genotype which grows faster may have a better environment because it is less likely to be shaded.

In controlled plant and animal breeding, efforts are made to randomize genotypes and environments, so that Cov_{GE} is minimized. In this situation, Cov_{GE} can be neglected, and

$$V_p = V_G + V_E$$

Conventionally,

$$V_G/V_p + V_E/V_p = h^2 + e^2$$

where h^2 and e^2 are the proportion of phenotypic variation due to genetic and environmental factors, respectively. The term h^2 is known as heritability in the broad sense,

$$h_B^2 = V_G/V_p$$

In practice the genetic variance is composed of a range of different interactions between loci, which may be additive, dominant, or epistatic. Variability in the narrow sense is defined as

$$h_N^2 = V_A/V_p$$

where V_A is the variance due to additive genetic factors. It is an important statistic in determining the rate and amount of response to directional selection in breeding programs.

Heritability is a population-specific measurement. It does not measure an invariant property of a particular trait but only the relative contributions of genetic and environmental differences to phenotypic variation in a specific situation. If either genetic or environmental variation changes, heritability estimates will also change; heritability measures the proportion of phenotypic variation in a particular population due to genetic variation.

Genetic and Phenotypic Variability

The assumption of the early geneticists that most populations carry little variation and that most individuals are homozygous at all but a few loci at which alleles are either recent mutants in the process of being eliminated by selection or maintained by opposing selection pressures or heterosis is clearly wrong. Evolutionary theory (requiring modifying genes to change phenotype expression) and artificial selection practice (revealing considerable potential for inherited response to selection) imply the existence of considerable genetic variation in and between populations. In the 1950s and 1960s assumptions about genetic load suggested there was a maximum amount of variation which could be tolerated in any population, but the application of protein and later DNA electrophoresis showed that load theory was too narrow and deterministic and led to reinterpretation so as to incorporate ecological factors (including heterogeneity in time and space and variable stress from biotic and abiotic agents). Empirical data have shown that even inbred organisms (such as obligate self-fertilizers) or ones living in an apparently constant environment (such as the deep sea) may still be heterozygous at a significant proportion of their loci (up to one-fourth for enzyme loci in plants and invertebrates and less for vertebrates).

The implications of load theory led to debate among population geneticists and evolutionists about the significance of the observed variation. Theoreticians impressed by the apparent rigor of load theory and biochemists not used to meaningful variation in their study of chemical pathways tended to dismiss the bulk of genetic variation as neutral and irrelevant to the organism, whereas evolutionary ecologists and practical breeders regarded it as potentially adaptive and as expected by Darwinian understanding. The latter emphasis has been shown to be correct: Far from being constrained by invariant genotypes, phenotypes can (and should) be treated as capable of rapid response to the environment and hence permissive rather than determinative of survival. A phenotype can be interpreted as the consequence of developmental reaction norms, facilitated in most cases by the width of its underlying genetic base.

This concept is supported by a series of experiments carried out by Bruce Wallace to test if radiation-induced mutations in *D. melanogaster* were inevitably detrimental. He found that mutations induced in flies made homozygous by artificial breeding were often heterotic, although mutations occurring in flies with a heterozygous background were usually deleterious to their carriers, presumably since their gene expression had been adjusted by normal selection. This led Wallace to emphasize the importance of balancing (or stabilizing) selection rather than the directed or cleansing selection which removes unwanted variants.

The concept of reaction norm incorporates the idea of phenotypic plasticity championed by Bradshaw and Levins in the 1960s and provides a much needed synthesis of allometry and ontogeny with ecological realism and fitness components. A particularly good example is the seasonal polyphenism of the African satyrine butterfly, *Bicyclus anyana*, studied by Paul Brakefield and colleagues. The wet and dry season forms of this species are phenotypically distinct in the size of the

eyespot and the banding patterns on the wings. Seasonal shifts in rainfall are associated with changes in temperature and with butterfly behavior. In the cooler dry season, the insects rest on dry grass or leaf litter and rarely fly; they do not breed at this time. In contrast, the adults fly actively in the warmer wet season, searching for mates and oviposition sites in the lush vegetation. Survival differences between the two forms suggest that cryptic matching is more important in the dry season and deception mediated by the false eyes in the wet season.

The wet season form arises through an acceleration of development which can result from an increased or fluctuating temperature, food quality, or hormonal influence. However, eyespot size and plasticity are affected by genetic variation as shown by variation between families in different temperature regimes and by directed selection. The switch between different wing spotting phenotypes in the butterfly *Maniola jurtina* studied over many years by E. B. Ford is probably also of this nature. Ford's extensive field studies showed the interaction between founder population differentiation, natural selection in particular localities, and environmental determinants, although he did not interpret them in this way. Unlike the *Bicyclus* case, the changes in phenotype in *Maniola* are small and unlikely to be important in survival or fitness (although it would be wrong to be dogmatic about this conclusion). However, they serve as a marker of a variable developmental system which may well have a range of functional responses. There are many such examples of trivial (or even wholly cryptic) differences between individuals which have different functional properties (e.g., the possession of B chromosomes or resistance to a newly introduced pesticide or pathogen).

The complicated response system in *Bicyclus* (and other butterflies) is similar in principle to the much simpler situation of eye pigmentation in the amphipod *Gammarus chevreuxi* studied classically by Julian Huxley and Ford. Here, the unpigmented, red-eye form is produced by a single mutant allele which has a slower rate of melanin synthesis than normal. However, pigmented eyes like the wild type arise if genetically red-eyed animals are raised at higher temperatures than normal or if they also carry a gene for small eyes which enables the small amount of pigment produced to cover the whole eye. Another example is the "himalayan" mutation of mammals frequently described in elementary genetics textbooks in which an unpigmented (white) coat becomes pigmented at the cold extremities (feet and ears), as in Siamese cats. Pigmentation may also develop in hair which grows in a shaved area which has a lower temperature than usual. The tyrosinase in this genotype is heat labile and has a maximum activity below normal body temperature. Rate genes of this nature have been very important in evolution and can be shown to produce major alterations in body form through various forms of allometry.

Phenotypes and Evolution

It is a truism that natural selection can only operate where phenotypic variation exists. Evolution results from changes in gene (strictly allele) frequencies, but these are the consequence rather than the cause of phenotypic differences. It follows that

selection on local forms (or ecotypes) which are solely the environmental consequence of a particular environment (e.g., plants grown in sheltered or exposed conditions or subject to a particular dietary lack or a behavioral reaction in an animal) will not lead to adaptive adjustment unless the phenotype in question depends on different genotypes. However, a phenotypic response to environmental conditions may allow a genetically nonadapted population to survive long enough to accumulate variants (through mutation, recombination, or immigration) and then adapt genetically. This idea was put forward independently by Baldwin (1896), Osborn (1897), and Lloyd Morgan (1900): It is commonly known as the Principle of Organic Selection or the Baldwin effect. This has been claimed by some to bridge the directed response which is the basis of Lamarckism and the random source of inherited variation which underlies Darwinism. Certainly, it may mimic Lamarckism, although it is of course wholly Darwinian in its operation.

Most of the early studies of phenotypic plasticity were carried out by botanists: Gaston Bonnier in the Alps and Pyrenees, F. E. Clements in Colorado and California, Turesson in Sweden, and Clausen, Keck, and Hiesey in California. However, the evolutionary implications were not pursued until Gause and Schmalhausen in Russia and Waddington in Britain began to examine the relationships between genotype, phenotype, and environment in animal experiments. They were able to show not only that natural selection could lead to a character originally induced by the environment becoming an inherited character (Waddington called this "genetic assimilation") but also that there is a causal connection between the environmentally induced change and subsequent genetic changes. They argued that since adaptability—the ability to acquire an adaptive variant during an animal's lifetime—has a genetic basis, the genes underlying flexible adaptive variations may ultimately be responsible for the evolution of fixed adaptations to a new environment, i.e., the environment is much more than a sieve selecting (or eliminating) chance mutations. These ideas have been criticized (notably by G. C. Williams) on two grounds: That most changes resulting from environmental challenges are not adaptive and that fixation of a genetic response results in a decrease in genetic potential because less (genetic) information is needed to specify a fixed, than a variable response. There is truth in both these objections, although the assumption that plasticity requires more inherited variation than a fixed state is debatable. However, there is no doubt that the link between stress-generated responses and subsequent adaptation requires more study. The problem historically is that ecologists have been primarily concerned with pattern (i.e., spatial relationships within communities), whereas evolutionists have concentrated on processes (i.e., temporal changes within communities), and both have used restrictive definitions of stress. This division between disciplines is not, of course, absolute, but it has led to a rift within population biology and a lack of understanding of coevolutionary possibilities and constraints.

The divergence between ecologists and evolutionists is seen in the models developed by each. In general, ecological models are self-contained because the dependent variables (numbers or density) and parameters (birth and death rates, dispersion differences, rates of predation, etc.) are all

measurable by ecological methods. Ecologists have been particularly concerned with identifying criteria for stability or fluctuation when species interact, for invadability, and for extinction when competition occurs. Such models are limited because the parameters are all manifestations of the phenotypic properties of individuals and hence the product of evolutionary processes. Although lip service is paid to the fact that phenotypes may change, in practice they are assumed to be effectively constant in ecological time. Evolutionary models originally concentrated on examining possible rates of evolution; then they became concerned more with the factors involved in the maintenance of genetic polymorphism. Their variables are the frequencies of alleles and genotypes; their parameters are relative fitnesses and rates of mutation, migration, and recombination. For a long time, fitnesses were regarded by the model builders as virtually constant, and it is only comparatively recently that the dependence of selection coefficients on density and frequency has been incorporated. This false assumption of constancy led to the problems associated with genetic load and to controversies over neutralism.

Genetical (evolutionary) models have become increasingly realistic and treat relative fitnesses as capable of varying in time and space as well as with gene frequency and population density. Such models are both genetical and ecological, and therefore they are intrinsically more informative than purely ecological ones. However, they still suffer from a major problem in that they tend to assume a degree of genetical equilibrium or stasis which is unjustified.

The way forward will be to increase ecological reality of evolutionary models, taking into account the characteristics of the niche for particular populations and communities, particularly any genetic constraints. Such models obviously need to include behavioral (sociobiological) input and the notion of evolutionary "strategies."

Taxonomy

Classification has become increasingly sophisticated with the increase in traits which can be used to characterize a group (or taxon). The problem is that conventional taxonomic (phenotypic) diversity may bear little relationship to genetic diversity. For example, the seaside sparrow (*Ammodramus nigrescens*) is common on the eastern and southern coasts of the United States. Nine subspecies have been described, including a rare and recently extinct (1987) dusky form, originally regarded as a separate species. Molecular analysis (based on mitochondrial DNA sequences) showed that the dusky sparrow was indistinguishable from other Atlantic forms, but that there was a major and previously unsuspected distinction between Atlantic and Gulf Coast groups.

In contrast, New Zealand tuatara lizards (*Sphenodon punctatus*) are conventionally treated as a single taxon, but molecular (and morphological) criteria indicate they comprise at least three species. For conservation management, it is obviously important that each taxon be considered separately.

There is no clear correlation between genetic and taxonomic diversity. The problems of classification that have always challenged museum workers have been compounded by the possibility of using genetic factors as additional or substitute taxonomic criteria: Closely related species in the genetic sense may have very different niches than those of their near relatives, whereas genetically more distant forms may look alike and interact strongly. There are no clear rules to link phenotype with genotype or phenotypic variety with genetic variety. There is plenty of scope for better multidisciplinary understanding of phenotypes, this will have to involve genetics, development, behavior, biotic and abiotic environments, life history, and phylogeny. Notwithstanding case by case examinations of the determinants and plasticity of the phenotypes in particular species and species groups are still needed.

Glossary

Chiasmata χ -Like configurations in meiosis.

Crossing-over Complex interaction of homologs within bivalents at pachytene resulting in reciprocal exchange of genetic material between nonsister chromatids.

Gene conversion A process of nonreciprocal (unidirectional) transfer of genetic information.

Genetic interference Interdependence of crossover events that includes chiasma interference (when an exchange in

one segment affects the probability of exchange in an adjacent segment) and chromatid interference (which determines the probabilities of chromatid configurations in successive pairs of chiasmata, i.e., the proportions of 2-, 3-, and 4-strand double exchanges).

Synaptonemal complex (SC) A three-part proteinaceous structure that affects the number and distribution of crossovers and converts crossovers into functional chiasmata.

Types of Recombination

There are various ways to classify different types of recombination. No matter how logical a classification system may seem, the simplest way is to compare alternative aspects (modes) of the general phenomenon of recombination. These modes may be based on types of participating cells (meiotic or mitotic and male or female), cell compartments (nuclear or mitochondrial), chromosomes and DNA sequences (homologous or nonhomologous), and types of exchanges (reciprocal or nonreciprocal).

Crossing-Over and Chiasmata

Two types of cell division are known for eukaryotic organisms: mitotic and meiotic. Recombination takes place in both. In cells that enter meiosis, the chromosomes have already undergone DNA replication so that each chromosome consists of two sister chromatids connected by a shared centromere. During the meiotic prophase, pairing of homologs brings about bivalent formation; each bivalent combines four chromatids. Complex interaction of homologs within bivalents at pachytene results in reciprocal exchange of genetic material between nonsister chromatids, a process referred to as crossing-over (Figure 1). Observation of corresponding meiotic stages (diplotene–diakinesis) reveals characteristic χ -like configurations called chiasmata. These configurations are interpreted as cytological manifestation of crossing-over. Chiasmata were observed and interpreted as a result of an unknown process of rejoining genetic material at the end of the nineteenth century, a decade before the discovery of partial linkage between genes in plants and two decades before Morgan's studies on crossing-over on *Drosophila*.

Nonhomologous Chromosome Segregation

After crossing-over occurs, chromosomes of each bivalent segregate independently relative to chromosomes of other bivalents in two consequent meiotic divisions. These two processes, crossing-over and recombination of nonhomologs, are characteristic of all sexual eukaryotes. With independent segregation, the ratio of parental and nonparental combinations of

corresponding alleles is 1 : 1, although a departure from independent assortment of unlinked genes, termed quasilinearage or pseudolinkage, was observed in both plants and animals, especially in interspecific hybrids (Korol *et al.*, 1994). Pseudolinkage is widespread in fish species, presumably reflecting the genome paleopolyploid nature (Danzmann *et al.*, 2008).

Mitotic Recombination

Exchange of genetic information can also occur during mitotic cell division, but it does so with a frequency of a few orders of magnitude lower than that of meiotic ones. The major exclusion from this rule is mitotic recombination resulting in high variation of somatic cells of the vertebrate immune system. Mitotic recombination may occur in the germline cells, for example, in *Drosophila* males where meiotic recombination is normally suppressed. Some genetic factors increase the rate of mitotic recombination manifold. For example, homozygosity for an inserted mobile element may result in high premeiotic recombination rates in *Drosophila* males comparable to that in female meiosis (Sved *et al.*, 1991). Mitotic crossing-over between the centromere and any locus results in two daughter cells homozygous for the entire segment distal to the site of exchange (Figure 2). This may have a strong negative impact if the initial cell was heterozygous for some detrimental alleles (*see* Applied Aspects).

Nonreciprocal Exchange

Normally, meiotic and mitotic crossovers are based on reciprocal physical exchange of genetic material between the parental chromosomes. Studies of recombination in fungi (*Sordaria*, *Neurospora*, and *Ascobolus*) have revealed a process of nonreciprocal (unidirectional) transfer of genetic information called gene conversion that accompanies reciprocal exchange (crossing-over). Gene conversion is based on DNA repair of mismatched strands along the "recombination tract." The demonstration of this process was due to the possibility of classifying marker segregation (spore color) of ordered spores in asci resulting from individual meiotic cells in hybrids between colored and wild-type strains. In addition to the expected regular 4 : 4 (colored : noncolored) octads, aberrant

Figure 1 Crossing-over at the four-chromatid stage: (a) Single exchange resulting in two parental (P1 and P2) and two recombinant (R1 and R2) chromosomes. (b) Double exchange involving nonsister chromatids, 2 and 3 at the crossover point in the short arm and 2–4 in the long arm – the result is one nonrecombinant (P1), two single-recombinant (R1 and R2), and one double-recombinant (R3) chromosomes. Note that if the same two nonsister chromatids participate in the exchange at both positions (e.g., 1–3 and 1–3) then two parental and two double-recombinant products will appear. Meiotic configurations involving all four chromatids in the double exchange (e.g., 1–4 at the first site and 2–3 at the second) will result in four single-recombination products.

Figure 2 Segmental homozygosity resulting from mitotic crossing-over: (a) A diploid heterozygote for a marker locus (M/m); (b) after DNA duplication each homolog is represented by two sister chromatids (the position of mitotic crossing-over between nonsister chromatids is marked by $\times$); (c) the structure of the homologs after crossing-over; and (d) the daughter cells resulting from mitosis are homozygous for the entire segment distal to the point of exchange.

ratios 2 : 6, 6 : 2, 3 : 5, and 5 : 3 are also observed, reflecting nonreciprocal exchange (*see* Genetic Control and Mechanisms of Recombination). The availability of sequence data for genes of several higher eukaryotic organisms (wild barley, maize, and *Drosophila*) allowed estimating population genetic parameters characterizing the rate of reciprocal (crossing-over) and nonreciprocal (gene conversion) recombination events, as well as the contribution of recombination and mutation to sequence variation at the population level. Both in outcrossing and self-fertilizing species, the contribution of gene conversion to total recombination may be twice as much as compared to crossing-over. Recombination, in total, contributes to sequence diversity no less than the mutation process (Morrell *et al.*, 2006).

Ectopic Recombination

Crossing-over occurring between homologous sequences of homologous chromosomes generates new genetic variation without changing genome structure. However, crossing-over may also involve homologous sequences of nonhomologous parts of the genome. This process is called ectopic

recombination. In particular, numerous families of repeated elements that are spread in eukaryotic genomes may participate in ectopic recombination. Retrotransposons can be especially active, either from nonhomologous chromosomes or from different sites of the same chromosome (giving rise to inter- and intrachromosomal ectopic recombination), resulting in chromosome rearrangements. In fact, the frequency of such events is very low, and it is unclear which mechanisms reduce this danger. One possibility may be a strong bias of recombination interaction in favor of gene conversion if such ectopic contacts occur. Ectopic recombination may also occur between such partners as chromosome and a plasmid, such as a 2- μ m plasmid in yeast harboring the gene for site-specific recombinase FLP and the tumor-inducing T-DNA segment of the Ti plasmid of *Agrobacterium tumefaciens* interacting with the host plant chromosome.

Illegitimate Recombination and Horizontal Transfer

Unlike homologous and site-specific ectopic recombination, illegitimate recombination is a process of joining DNA

molecules that have only a small sequence homology. Illegitimate recombination is common in nature, especially in interactions between retroelements and host genome DNA and in some host–parasite systems. One of the most common examples is the previously mentioned interaction between bacteria, such as *A. tumefaciens*, and their host plants mediated by the bacterial plasmid transformation (see Ectopic Recombination). Although this process can be considered as a “physiological” rather than a genetic transfer, it may also have evolutionary consequences as one of the mediators of horizontal gene transfer. Illegitimate recombination is involved in many situations of foreign DNA integration in direct transformation experiments aimed at obtaining genetically engineered (transgenic) organisms.

Extranuclear Recombination, Exchanges between Cell Compartments

Recombination was proven to affect the organization of mitochondrial DNA. Mitochondrial recombination was detected in *Drosophila*, mussels, and various vertebrate species including fishes, birds, and mammals (Tsaousis *et al.*, 2005). Convincing evidence of widespread recombination in mitochondrial genomes has been obtained for plants. In fact, a specific substrate for frequent mitochondrial recombination was discovered and sequenced in a few plant species. Especially interesting from the evolutionary point of view are putative DNA exchanges between different cell compartments: nuclear–mitochondrial, nuclear–chloroplast, and mitochondrial–chloroplast. Many such sequences demonstrating “chloroplast → mitochondrial” transfer were obtained for cereals. The existence of mitochondrial recombination limits the validity of evolutionary reconstructions based on a certain part rather than on the entire mitochondrial genome.

Basic Features of Reciprocal Homologous Recombination (Crossing-Over)

Recombination Rate and Map Distance

The average number of crossovers in a given segment represents its genetic length. Correspondingly, genetic distance between two loci can be defined as the average number of recombination events occurring in the segment. Therefore, for loci flanking a unit length segment one exchange per meiosis is expected on average, resulting in 50% recombinant gametes. This notion of genetic distance serves as a basis for gene mapping. Two fundamental facts make genetic mapping possible: (1) linear organization of genetic material in chromosomes and (2) increasing recombination rate between loci with the increase in their physical distance. Map distance is of additive nature: For any subdivision of a segment, the segment length is the sum of lengths of its subintervals. A limitation of map distance as a measure is that it cannot be estimated directly: an odd number of exchanges in a segment marked by two loci leads to the appearance, in the progeny, of the same recombinant genotypes as those resulting from one exchange, whereas an even number results in no observable recombinants. Recombination frequencies (rf s) estimated

from the observed proportions of recombinant and non-recombinant individuals coincide with map distances only for short segments when multiple exchanges can be ignored. Therefore, transformation of experimentally estimated rf values into map distances (x) is needed. Relations of the form $rf = rf(x)$ are referred to as mapping functions.

Genetic Interference and Mapping Functions

Multiple exchanges are relatively rare among eukaryotes. These vary between one and three for the majority of higher organisms, with five or six rarely occurring, although values up to 12 have been reported (Korol *et al.*, 1994). In *Drosophila*, the frequency of tetrads with four or more crossovers is extremely low (usually much less than 1%).

Interference: Its Measurement and Basic Properties

Consider two adjacent marked segments m1–m2 and m2–m3 with recombination rates rf_1 and rf_2 . If exchanges in adjacent segments occur independently, the probability of a double exchange within m1–m3 can be determined as $rf_{12} = rf_1 rf_2$. Under the same assumption, recombination frequency rf_3 between loci m1 and m3 is given by

$$rf_3 = rf_1(1 - rf_2) + rf_2(1 - rf_1) = rf_1 + rf_2 - 2rf_{12}$$

Much evidence indicates that the observed frequency of double crossovers usually differs from the expected one, a phenomenon termed as genetic interference. The degree of interference is measured by the coefficient of coincidence (c):

$$c = \frac{rf_{12}(\text{observed})}{rf_{12}(\text{expected})} = \frac{rf_{12}(\text{observed})}{rf_1 rf_2}$$

The existence of interference was shown both genetically and cytologically. It is ubiquitous in eukaryotes. To date, only in a few species (*Shizosaccharomyces pombe*, *Aspergillus nidulans*, *Tetrahymena thermophila*, and possibly *Ustilago maydis*) has recombination been found to proceed with no interference (Loidl and Scherthan, 2004, and references therein). If the occurrence of crossing-over in one segment reduces the probability of exchange in an adjacent segment ($c < 1$), then it is positive interference; when one exchange increases the frequency of another ($c > 1$), it is negative interference. The nematode *Caenorhabditis elegans* is an example of extreme positive interference: a single crossover formed per chromosome suppresses formation of additional exchanges.

Two types of interference have been distinguished: chiasma interference, in which an exchange occurring in a segment affects the probability of another one occurring in an adjacent segment, and chromatid interference, which determines the pattern of chromatid configurations in successive pairs of chiasmata in a bivalent (i.e., the proportions of two-, three-, and four-strand double exchanges) (Figure 1). In the absence of chromatid interference, the ratio should be 1:2:1. Evidence of chromatid interference is scarce. Chiasma interference determines the pattern of distribution between successive exchanges along a chromosome. The amount of interference within a segment depends on its distance from the centromere. Near the centromere, interference between exchanges in the adjacent segments of the same chromosome

arm is maximal. It is generally believed that no interference exists across the centromere, although many exclusions are known.

Mapping Functions

Positive interference ($c < 1$) is a widespread phenomenon. It was found that in many cases the approximation $c(rf) = 2rf$ (Kosambi interference) fits the data well (i.e., $c \approx 0$ at small distances and $c \approx 1$ at large distances). The corresponding mapping function

$$rf = 0.5 \tanh(2x) \quad \text{or} \quad x = 0.25 \ln((1 + 2rf)/(1 - 2rf))$$

appeared to be a good approximation for *Drosophila*, rice, mouse, and other eukaryotes. The formula for rf values in adjacent intervals, corresponding to Kosambi's function, takes the following form:

$$rf_3 = \frac{rf_1 + rf_2}{1 + 4rf_1rf_2}$$

Situations with no interference can be represented by the mapping function proposed by J. Haldane:

$$rf(x) = 0.5(1 + e^{-2x})$$

Some results indicate that negative interference (i.e., an excess of double exchanges over the level expected with the assumption of independence), may also occur. Such data were observed for *Drosophila* and some plants, fungi, and viruses. One should take into account that values of $c > 1$ can also result from marker scoring errors and data pooling, owing to heterogeneity of individual rf values.

Distribution of Crossovers within Eukaryotic Chromosomes

The efficiency of crossing-over strongly depends on between- and within-chromosome patterns of exchange distribution in the nucleus. Here, two different (albeit related) problems are generally distinguished: (1) crossover distribution in relation to major components of the chromosome, that is, the centromere, telomeres, heterochromatin (intensively stained cytological segments of chromosomes – gene-poor regions), and euchromatin (faintly stained gene-rich regions), and (2) relative positions of crossovers with respect to one another. These questions were thoroughly studied based on scoring recombination events between multiple markers and complemented by cytological observations. A wide range of spatial variation in exchange frequency was revealed – from long stretches of heterochromatin in which crossing-over is almost blocked to short segments containing recombination hotspots (see Recombination Signals, Hotspots of Recombination, and Transcription). Heterochromatic blocks affect the distribution of crossovers in the entire genome. Recombination non uniformity of the chromosomes was first established in *Drosophila* and then confirmed in a wide range of organisms. Thus, in the B genome of wheat the physical length of DNA per exchange varies more than 150-fold along the chromosome (Lukaszewski and Curtis, 1993). In the centromeric region of the human X chromosome, the recombination rate is at least eight-fold lower than the average rate of female recombination on the X chromosome.

The Effects of Sex

By the Haldane–Huxley rule, if crossing-over is strongly suppressed or lacking in meiosis of one of the sexes, then that sex is invariably the heterogametic one. The effect of sex on rf has been established in a variety of animal species, with this rule holding in all cases of alternative (all-or-none type) sex differences. Provided crossing-over occurs normally during the formation of both male and female gametes, then rf in the heterogametic sex may be either lower or higher than that in the homogametic one, with the sign and magnitude of sex difference in rf being segment specific. Sex differences in recombination have also been revealed by cytological analysis. Higher female recombination was observed in many species. In humans, the total length of female maps is nearly twice as long as that from male maps; in some regions (mainly subtelomeric ones), the opposite tendency is observed. Most of the examined genomic regions in maize exhibit higher male recombination or no difference; the extent of the difference (if it exists) may strongly depend on the genotype. A substantially higher crossing-over rate in male compared to female meiosis has been found in *Arabidopsis* (Korol *et al.*, 1994). This is also true for some animals exhibiting a higher degree of linkage and/or more localized pattern of exchange distribution in the homogametic sex than in the heterogametic one, such as marsupials (Trivers, 1988).

The mechanisms responsible for differences in rf between male and female meiosis are unknown. In most animals, sex is determined by a certain chromosome. Thus, it can be suggested that the difference between male and female meiosis is controlled by genes located on this chromosome. Alternatively, sex chromosome can canalize the development of general physiological (biochemical) sex differences (e.g., in the hormonal status) in a toggle-like manner, with specific recombination features of male and female meiosis being a secondary effect of the main regulator. The latter suggestion is supported by data from the fish *Oryzias latipes* in which the heterogametic sex is represented by XY males (Yamamoto, 1961). When males XY were transformed into functional XY females by a hormonal treatment, rf increased by a factor of 5 compared to the level in normal males. In humans, it was found that the distribution of sex difference in rf is related to genomic imprinting manifested in region-specific differential modification (methylation) of parental alleles. We speculated that gametic selection may be an important contributing factor to the evolution of sex differences in recombination (Korol *et al.*, 1994). Lenormand and Dutheil (2005) supported this hypothesis by a detailed analysis of available evidence on many species.

The Effects of Environmental Conditions

If diversity is essential to population survival, it would be highly adaptive for organisms to increase genetic variation in challenging (stressful) environments and decrease it under optimal conditions (Korol *et al.*, 1994). Such regulation should increase the chances of population survival without dissipation of the accumulated hidden genetic variation in favorable times. An abundance of evidence on environmental modulation was found for the main sources of variation:

mutation, chromosomal rearrangements, transposition of mobile elements, and recombination. The environment can affect recombination in two ways. Firstly, it can affect recombination indirectly when changes in the frequency of alleles at recombination controlling loci depend, through a feedback mechanism, on changes in the frequency of the selected (fitness-related) loci (*see* Evolution of Recombination). Secondly, it can affect recombination directly when in response to environmental factors, the organism modifies (within genetically determined limits) the value of rf , that is, when not rf but the norm of reaction with respect to rf is genetically determined. The fact of direct influence of the environment on recombination has long been known in genetics. As early as 1917, H Plough observed in *Drosophila* a U-shaped dependence of rf on temperature: Recombination was minimal at optimum temperature and increased with the departure of temperature from the optimum. Similar data indicating an increase in recombination level with deteriorating environment have been reported in many works. Extreme conditions also tend to reduce interference.

Ontogenetic Memory and Transgeneration Effect

A common belief is that environmental factors may affect recombination only when the treatment occurs during a relatively short period between premeiotic S-period and prophase of the first meiotic division. Therefore, in many organisms the sensitive stage may comprise a very small part of the life cycle. Does it mean that environmental stresses on earlier stages of the development cannot affect recombination? Some limited evidence available for a few organisms indicate that just the opposite may be true. Neel (1941) studied the effect of severe starvation of *Drosophila* larvae on meiotic recombination. An increased rate of recombination in chromosome 3 was observed during the whole lifetime of the females, representing some memory of starvation-induced changes in germline cells during many mitotic cell divisions until meiosis. Zhuchenko *et al.* (1983) showed that temperature stress applied to *Drosophila* F1 hybrids at the embryonic stages can affect the rate of meiotic recombination during the entire lifetime of F1 females, implying that stress-induced changes survived many divisions of germline cells until meiosis. In *S. pombe*, X-irradiation caused an increase in the recombination rate which persisted for 8–10 cell generations after irradiation (Takeda *et al.*, 2008). Limited data indicate that the memory of stress-induced changes may extend over generations. In experiments of Landner (1970) with *Neurospora*, temperature treatments applied as early as 3–4 days before fertilization, affected the rate of meiotic recombination, that is, in the next generation. A similar transgeneration effect was also found in the aforementioned study of Zhuchenko *et al.* (1983) with *Drosophila*: changes in meiotic recombination rate were recorded in F1 females whose wild-type mothers were subjected to heat treatment of 36 °C for 12 h.

Somatic recombination is considered a general plant response to environmental stresses like UV, high temperature, herbicides and other factors, but the usual expectation is that stress-induced stimulation should disappear together with the inducing factor (Pecinka *et al.*, 2009). Experiments with *Arabidopsis* have shown that this may not be the case: treatment with UV light or with a chemical mimicking pathogen

attack caused increased somatic recombination in leaves of the treated plants and of several subsequent generations (Molinier *et al.*, 2006). These findings were interpreted by the authors as a manifestation of the epigenetic effect. Using ten different physical and chemical stress treatments, Pecinka *et al.* (2009) tried to repeat these results on several lines of *Arabidopsis* by scoring for somatic recombination in the treated (S0) and subsequent generations of selfing (S1 and S2). The results were negative: despite highly significant induction observed in S0, only small and nonconsistent effects were observed in S1 and S2, suggesting that the transgeneration effect in *Arabidopsis* is not a rule and occurs only under very special conditions. Obviously, a similar question of reproducibility should also be addressed for stress memory related to meiotic effects.

Feedback Regulation of Genetic Variation

If stress may be recombinogenic, it is natural to assume that the degree of the effect should depend on the intensity of the stress, that is, the degree to which an individual is stressed. In other words, induced changes in recombination in maladapted genotypes should be higher than in well adapted ones (Zhuchenko and Korol, 1983). Experimental evidence for the last principle has been obtained in the author's lab for *Drosophila* and tomato (reviewed by Korol *et al.*, 1994). In *Drosophila*, the increase in male recombination induced by heat treatment was negatively correlated with flies' resistance to high temperatures. In tests with tomato varieties and their F1 hybrids, low temperature did not increase the chiasma frequency in cold-resistant varieties and in their F1 hybrids, whereas the reverse was true for cold-sensitive genotypes. By contrast, elevated temperatures caused an increase in recombination only in heat-sensitive genotypes. Populations may benefit from such a feedback mechanism by generating additional variation to meet new, challenging conditions while preserving previously evolved adaptive gene combinations, when there is no need for additional variation, thereby reducing the recombination load. In the last decade, the concept of plastic- and fitness-associated recombination has become the subject of theoretical studies (Hadany and Beker, 2003). Theoretical models and growing evidence indicate that similar strategies may also be relevant to other systems affecting genetic variation: transposition of mobile genetic elements, DNA repair, mutation rate, and sexual versus asexual reproduction (e.g., Lupu *et al.*, 2006; Agrawal and Wang, 2008; Schoustra *et al.*, 2010).

Genetic Control and Mechanisms of Recombination

Selection for Changed Recombination, Genetic Modifiers of Recombination

Selection for altered recombination proved an important tool in analyzing genetic control of recombination. Such experiments have been conducted on dozens of organisms, including *Drosophila*, flour beetle *Tribolium castaneum*, grasshopper *Schistocerca gregaria*, silkworm *Bombix mori*, lima bean, and fungi *Neurospora* and *Schizophyllum* (Korol *et al.*, 1994). These experiments complemented the numerous findings on the existence of a considerable amount of genetic variation in

rf in natural and laboratory populations (*see* Intraspecific Variation for the Rate of Recombination) available for selection to act on. The effectiveness of directional selection for altered *rf* has been shown to depend on the segment under study, the size, structure, and origin of the start population; the breeding system; the estimation procedure; and the intensity and duration of selection. Genetic analysis of the accumulated differences between selected lines enabled the question of the genetic basis of variation in recombination to be addressed. In as few as 10 generations, divergent selection for *rf* in the p-Y region of silkworm chromosome 2 succeeded to produce lines with *rf*=37–39% and 5–7%, starting from 25.6%. The obtained evidence suggests that recombination (frequency and distribution) in eukaryotic genomes is under complex control of polymorphic modifiers with small to moderate effect. The rate of recombination in a given region may depend on both linked modifiers and genes located on other chromosomes.

Meiotic Mutants as an Analytical Tool in Recombination Studies: Overlapping of DNA Repair, Recombination, and Segregation Systems

The first discovered point mutation (in 1922) affecting recombination was *Drosophila* gene c(3)G, which almost completely blocks crossing-over in females. During subsequent years, many other genes with strong effect on different meiotic steps and recombination were isolated in eukaryotes (mainly in fungi, *Drosophila*, maize, and recently *Arabidopsis* and the nematode *Caenorhabditis elegans*). The availability of diverse mutants affecting the coordinated steps of meiosis and recombination allowed a detailed cytogenetic characterization of meiosis (reviewed by Heyer *et al.*, 2010). These include commitment to meiosis, regulation of major steps in chromosome conjugation and formation of the synaptonemal complex (SC) (*see* Ultrastructure of Recombination: SC and Recombination Nodules (RN)), DNA breaks formation and strand exchange, chiasma maintenance, and chromosome disjunction. The broad network of recombination–meiosis mutants identified in yeast and other fungi, *Drosophila*, *C. elegans*, and *Arabidopsis* serves as a basis for cloning recombination genes and studying the molecular mechanisms of recombination. Numerous results were obtained on this rich material showing a deep overlapping of pathways related to DNA recombination and DNA repair. Thus, mutations for loci controlling meiosis and recombination also tend to exhibit disturbed repair functions. Such a duality seems to be an ancient phenomenon. In prokaryotes, the best example is the RecA protein of *Escherichia coli* that is involved in early stages of recombination and, simultaneously, in induced SOS repair. Recombination is also strongly affected by mutations in genes controlling other enzymatic steps in DNA metabolism, for example, replication. Genes for DNA repair and recombination exhibit a high degree of sequence, structural, or functional similarity throughout life. This conservation was established using a combination of genetic and cytological methods with molecular cloning, sequencing, and genetic transformation. Thus, defects in the recombination–repair system of one species may be complemented by a gene transferred from another species, sometimes a distant one

(e.g., from a prokaryote to eukaryote). However, this does not exclude high interspecific differences in many important features of recombination (Korol *et al.*, 1994).

Comparison of recombination in meiotic mutants and in corresponding wild-type genotypes provides an interesting conclusion. It appears that genomic distribution of exchanges in normal meiosis is more restricted, less random, than in meiosis altered by mutations, indicating that these restrictions are largely a result of evolutionary adjustment of recombination. Meiotic mutants tend to lessen the restrictions, and regions normally excluded from exchanges become involved in crossing-over. Simultaneously, a reduction of interference is also observed despite a general tightening of linkage (Bhagat *et al.*, 2004). In meiotic mutants, the correspondence between physical and recombination length of chromosome segments becomes closer. In many cases, mei mutations referred to as hyper-rec can significantly enhance crossing-over (and not only in specific regions) or increase the rate of multiple exchanges, intragenic recombination, and/or mitotic crossing-over manyfold.

The meiotic system manifests a close connection between homologous conjugation, crossing-over, and regulation of chromosome segregation. This association is invariable for normal meiosis and served as a basis for the view that regulation of chromosome segregation is one of the main functions of crossing-over. Meiotic mutants were isolated where the two phenomena, segregation and recombination, are not coupled. For instance, crossing-over is normally almost completely suppressed in chromosome 4 of *Drosophila melanogaster*. Some mei-mutants with reduced recombination and/or altered exchange distribution within large chromosomes exhibit crossing-over within chromosome 4 and disturbed segregation of this chromosome (Sandler and Szauter, 1978).

Ultrastructure of Recombination: SC and RNs

Electron microscopy reveals meiosis-specific organization of chromosome associations at the meiotic prophase I. A three-part proteinaceous structure, called SC, is initiated at the zygotene stage, maintains the paired homologs together during pachytene, and disappears at the diplotene. Short stretches of DNA of the homologs are involved in the central part of SC where intimate molecular pairing takes place. SCs are considered as structures that affect the number and distribution of crossovers and convert crossovers into functional chiasmata. In many species (e.g., human, mouse, zebrafish, and *Arabidopsis*), the difference in total lengths of SCs in male and female meiocytes is correlated with the difference between male and female recombination map lengths. Small electron-dense bodies, RNs, were detected within the central part of the SC. Early RNs that appear before pachytene are more or less evenly distributed along the bivalent and are supposed to participate in synapsis. Late, or pachytene, RNs seem to represent recombination enzymes associated with exchanging DNA molecules. The distribution of late RNs corresponds well to chiasma distribution and is believed to represent the sites for recombination. Numerous meiotic mutants were tested with respect to their ultrastructural and molecular phenotype – the morphology and biochemistry of SC. An interesting fact

is that only in a few organisms was meiotic recombination normally found without SC (*S. pombe*, *A. nidulans*, *T. thermophila*, and possibly *U. maydis*). However, in many cases SC was found in achiatic meiosis (with no recombination). In *S. pombe* and *A. nidulans* with recombination occurring without SC, the frequency of exchanges per bivalent is high, and especially interesting is the absence of interference. Thus, the absence of SC may allow for more reshuffling of the homologs. Analysis of SC appeared to be an important tool in determining the causes of altered fertility in farm mammals.

Molecular Mechanisms of Recombination

When considering molecular mechanisms of recombination in eukaryotes, a broader spectrum of basic processes involved may also be addressed, including chromosome conjugation and segregation. This is partly due to the prevailing experimental methodology based on analyzing cytogenetic and molecular effects of numerous mutants defective for meiosis–recombination and DNA repair. Historically, the studies of molecular mechanisms of recombination in prokaryotes served as the main source of models to be tested in eukaryotes. The basic enzymatic activities involved in prokaryote recombination include those of endo- and exonucleases, strand transfer, DNA unwinding, ligation, and resolving Holliday's heteroduplex structure. Eukaryotic analogs were found and (are to be) characterized in the best-studied eukaryotes, such as yeast, *Drosophila*, *Arabidopsis*, and mammals. Clearly, eukaryotic recombination systems are supposed to be more complex due to additional problems related to meiosis, such as homologous pairing and segregation.

The classical concept of molecular recombination included the following steps: (1) intimate pairing of homologs; (2) formation of single-strand DNA nicks at homologous sites and local denaturation of double-stranded DNA; (3) formation of recombination intermediate (Holliday junction) by reciprocal strand transfer and renaturation, its migration from the initiation site, and heteroduplex formation (with local mismatched DNA due to heterozygosity of the parental chromosomes); and (4) resolution of the Holliday structure, either after or before isomerization. In the first case, the content from both sides of the considered regions remains unchanged, whereas in the second case it results in reciprocal exchange. In both cases, the mismatched positions should undergo correction. Depending on the strand used as a template in the repair process, two alternatives will be observed: recovering the initial state and nonreciprocal information transfer (gene conversion).

A new understanding of eukaryotic recombination mechanisms resulted from the discovery of the leading role of double-strand DNA breaks (DSBs) in yeast (Szostak *et al.*, 1983) that became the leading concept (Szostak model) of crossover formation for more than two decades. Details on different pathways related to this process were also studied in mammalian cells, *Drosophila*, and plants based mainly on recombination–repair mutants. Another strategy is to study specially engineered genetic models with a modified recombination system (Shalev *et al.*, 1999). Homology of recombination genes in one species to genes controlling

DSB-dependent recombination in yeast may be indicative for a shared DSB mechanism of recombination initiation, as exemplified by the *Drosophila* mei-W68 gene and yeast Spo11 (McKim and Hayashi-Hagihara, 1998). However, new evidence obtained on different organisms points to limitations of the Szostak model that focused only on the crossover-formation pathway of recombination, whereas new models take into account the noncrossover pathway (potentially leading to gene conversion) and explain details of DSB initiation in both pathways and their interference-sensitive and -insensitive classes (reviewed by Cromie and Smith, 2007; Heyer *et al.*, 2010). In particular, recent studies on the fission yeast *S. pombe* point to the existence of a novel mechanism for the regulation of crossover distribution along the chromosome – controlled repair of DSBs based on partner choice model (differential interaction with the sister chromatid or with the homologous chromosome) (Hyppa and Smith, 2010). This mechanism explains the rather high stability of the crossover rate per DNA physical unit length despite high variation of the DSB rate along the genome. The molecular mechanisms of DSB repair involved in meiotic and mitotic recombination differ in many aspects (for a recent review see Andersen and Sekelsky, 2010).

Recombination Signals, Hotspots of Recombination, and Transcription

Although recombination occurs all over the genome, the accumulated data points to the existence of hotspots and cold spots of recombination. In certain cases, highly specific interactions were found between recombination–repair mutations and “signal” DNA sequences resulting in a sharp increase in *rf* within defined genomic segments. The best-known recombination signal is the octamer 5'GCTGGTGG-3' of *E. coli* referred to as χ element. Heptamer 5'ATGACGT-3' is known as a meiotic recombination hotspot of fission yeast *S. pombe*. A few recombination hotspots have been characterized in mammals, with the major histocompatibility complex being one of the best-known examples. In humans, 8-oxoguanine, resulting from endogenous oxidative stress, is a hotspot signal spread over thousands of positions in the genome. In humans and *Drosophila*, a 13-bp sequence motif CCNCCNTNNCCNC is associated with hotspots of fine-scale recombination (Stevenson and Noor, 2010). Recent studies on humans and mice showed that a major player for hotspot specification is PRDM9 gene (Baudat *et al.*, 2010). PRDM9 is predicted to recognize the mentioned 13-mer motif. Allelic variants of PRDM9 zinc finger region are significantly associated with variability in genome-wide hotspot usage among humans, indicating that the binding of PRDM9 protein to specific DNA sequences controls the initiation of recombination at specific locations in the genome. The minisatellite structure of the PRDM9 zinc finger region points to its potential to increase variability leading to new PRDM9 variants with new DNA binding specificities, hence new genome-wide distributed hotspots.

In eukaryotes, mobile elements may act as recombination enhancers. Thus, with identical locations on homologous chromosomes, a pair of P elements of *D. melanogaster* can induce recombination at a frequency of 20% in males in

which recombination is normally absent (Sved *et al.*, 1991). This effect serves as a basis for an efficient method of fine genetic mapping, in which P elements are used to promote recombination at their insertion sites. However, usually *Drosophila* genome regions with increased density of transposable elements display reduced recombination. In general, both positive and negative correlations between the abundance of transposable elements and the recombination rate were found in eukaryotic organisms. The accumulating evidence indicates that recombination hotspots are associated with DSB sites, depend on chromatin organization, and are influenced by epigenetic changes.

In the 1960s and 1970s, it was speculated that initiation of recombination is attached to transcription promoters (Whitehouse, 1966). In moving from lower to higher organisms, the recombination density over the genome is reduced by three or four orders of magnitude with no marked trend in structural genes. Thuriaux (1977) attributed this paradox to preferential localization of recombination in structural genes. It was suggested that the requirement for common specific changes in chromatin organization may cause an overlapping in control of transcription, recombination, repair, and mutation (Whitehouse, 1966; Thuriaux, 1977; Korol *et al.*, 1994; Laurencon *et al.*, 1997). The evidence from many eukaryotes indicates that regions with high *rf* correspond to gene-rich regions (Lichten and Goldman, 1995), although an opposite trend was found in *C. elegans*. The results obtained during the past decades for yeast (*Saccharomyces cerevisiae* and *S. pombe*) support the idea of recombination–transcription relationships, but also show their complicated nature. In particular, genes near hotspots display a higher expression level, but not in meiosis when their expression is lower. It appeared that upstream gene sequences acting as transcriptional control sites may also play a role of inducible recombination hotspots. This implies that environmental effects on recombination reflect

partially overlapping environmental regulation of transcription and recombination (Koren *et al.*, 2002). In humans, increased meiotic recombination coincides with high GC and gene-rich regions, but recombination rate within genes is lower compared to their upstream and downstream regions (Coop *et al.*, 2008). Surprisingly, a negative correlation was found between crossover rate and gene expression in meiosis (McVicker and Green, 2010).

In general, the available information shows high intragenomic heterogeneity and nonrandomness of recombination. These are caused by a hierarchical control system that involves interaction of a complex web of recombination–repair genes with peculiarities of macro- and micro-organization of the genetic material (Table 1). The important role of gene distribution in this regulation indicates its adaptive role in the evolution of genetic systems.

Biodiversity of Recombination Systems

Evolutionary Trends in Genomewide Recombination Rate

A considerable (by several orders of magnitude) decrease in *rf* per unit physical length of DNA is observed when moving from prokaryotes and lower eukaryotes to higher organisms (Thuriaux, 1977). Even among eukaryotes, the density of recombination events within the genome varies widely (Table 2). The genetic length of the genome varies less and strongly depends on haploid chromosome number. A relatively low correlation is displayed by fine-scale recombination rates in genomic regions with parallel syntenic blocks of different species pointing to fast evolution of recombination hot spots. This is reflected in human-chimpanzee comparisons and even among different human populations. But at larger scales, including the genome level, recombination rates are

Table 1 Hierarchical control of recombination events

System effects:

- Control of the nucleus as a whole, manifested in the classical *interchromosomal effect* of rearrangements, as well as effects of eu- and aneuploidy and supernumerary (*B*) chromosomes
- Effect of chromosome size
- Regulation based on cytonuclear interactions
- Sex differences in recombination frequency and distribution
- Effect of environmental conditions (stress) and age
- Position of euchromatin (as main target for recombination) relative to the centromere, telomeres, and heterochromatic blocks

DNA sequence organization of the target region:

- Heterozygosity for micro- and macroinversions, deletions, and translocations
- Microsite organization of DNA sequences including distribution of specific regulatory sequences like recombination hotspots, micro-, and minisatellites
- Distribution of epigenetically modified (e.g., methylated) DNA stretches
- Effects of mobile genetic elements
- Distribution of gene-rich islands

Genes controlling DNA metabolism:

- Genome-, chromosome-, and segment-specific effects of major *rec*-genes of the *coarse control* system affecting the basic steps in recombination mechanics (pairing, DNA strand exchanges, recombination repair)
- Segment-specific regulation of crossover frequency by genes of the *fine control* system with relatively small effects of individual components
- Genes encoding active transposases

Interaction of factors both within and between the foregoing groups plays an important role in observed patterns of recombination frequency and distribution within genome and its variation within and between species.

Table 2 Recombination characteristics of some eukaryotic genomes

Species	Genome length (cM)	Haploid number (n)	Chromosome length (cM)	kb:cM ratio
<i>Magnaporthe grisea</i>	600	7	85	80
<i>Pinus taeda</i>	1700	12	140	12,000
<i>Arabidopsis thaliana</i>	600	5	120	230
<i>Brassica rapa</i>	1900	10	190	280
<i>Phaseolus vulgaris</i>	1200	11	110	530
<i>Hordeum spontaneum</i>	1200	7	170	4000
<i>Lycopersicon esculentum</i>	1400	12	120	900
<i>Drosophila melanogaster</i>	300	4	75	570
<i>Bombix mori</i>	3400	28	120	130
<i>Tribolium castaneum</i>	600	10	60	350
<i>Apis mellifera</i>	3700	16	230	45
<i>Danio rerio</i>	2900	25	120	590
<i>Gallus gallus</i>	3200	29	110	310
<i>Monodelphis domestica</i>	650	9	70	5400
<i>Mus musculus</i>	1400	20	70	1800
<i>Canis familiaris</i>	2100	39	54	1200
<i>Homo sapiens</i>	3600	23	160	800

well correlated. Higher “regularity” of recombination due to frequent outcrossing, the obligatory occurrence of at least one exchange per bivalent, and increasing genome size are considered to determine the evolutionary importance of recombination in higher sexual eukaryotes. In lower organisms, recombination was supposed to play a less important role due to a slight chance of sexual contacts between individuals (Maynard Smith *et al.*, 1991). Consequently, natural populations of such species should manifest a clonal structure, with strong correlation (linkage disequilibrium (LD)) between alleles at different loci. However, this may not be the case in some protozoan species, such as malaria *Plasmodium falciparum* (Conway *et al.*, 1999). The revealed population pattern of *P. falciparum* includes high polymorphism and a rapid decay of LD with distance (reaching independence between polymorphic sites of 0.3–1.0 kb) that looks like that of higher sexually reproducing eukaryotes.

Intraspecific Variation for the Rate of Recombination

The analysis of genetic variation of recombination parameters allows a deeper insight into patterns, mechanisms, and the evolutionary role of recombination. The genetic differences in crossing-over rate seem to have been originally established by Sturtevant in 1913 who discovered modifiers sharply reducing crossing-over during oogenesis in heterozygous females of *Drosophila*. Later, he suggested these to be inversions, a prediction that was subsequently confirmed by cytological analysis of salivary gland chromosomes. Among point mutations affecting recombination, the first to be discovered was c(3)G, which almost completely blocks crossing-over in *Drosophila* females. Additional studies demonstrated high genetic variation in *rf* in *D. melanogaster* and other *Drosophila* species (Korol *et al.*, 1994; see Meiotic Mutants as an Analytical Tool in Recombination Studies: Overlapping of DNA Repair, Recombination, and Segregation Systems). Recombination studies in *Drosophila ananassae* males revealed high variation in crossing-over rate in the second and third chromosomes;

individual *rf* values in the ml-ru segment of chromosome 3 varied between 2.2% and 42.8% (i.e., 20-fold). Differences between maize plants in *rf* in the sh-su-wx segment increased as the degree of relatedness decreased and there was correspondence between micro- and macrosporogenesis. Polymorphism for B chromosomes (also known as supernumerary chromosomes) and heterochromatic knobs and their interaction play a significant role in the variation of *rf* in maize. B chromosomes affect pairing and crossing-over in many plants and animals.

Abundant evidence for intraspecific genetic variation in crossing-over rate and/or chiasma frequency is available for many eukaryotes, both lower (*Coprinus*, *Schizophyllum*, *Neurospora*, *Saccharomyces*, and *Sordaria*) and higher (pearl millet, pea, jute, ryegrass, barley, wheat, tomato, snails, silkworm, grasshoppers, locusts, flour beetle, lizards, mouse, rat, and cattle) (Korol *et al.*, 1994). Human variation in fine-scale recombination patterns among individuals was examined based on dense genome-wide single-nucleotide polymorphism data in nuclear families (Coop *et al.*, 2008). Similar recombination hot spot usage in male and female meiosis was found combined with high heritable variation in the proportion of crossovers detected in these hotspots. Intraspecific variation in recombination rate and genomic distribution may be of primary importance in a better understanding of the evolution of recombination, genetic basis of biodiversity in natural systems, optimizing genetic conservation and breeding strategies, designing experiments on genetic mapping of complex traits, and map-based cloning.

Recombination and Domestication Evolution

Two questions are of major interest when discussing the interface domestication–recombination: (1) How have recombination features of the progenitors affected the pattern of selection response and selection advance? (2) How has selection for domestication traits affected the recombination system? Despite many theoretical studies on the interaction

between selection and recombination, the very limited available evidence concerns only a few organisms out of a few hundred domesticated plant and animal species. Burt and Bell (1987) studied the relationship between male chiasma frequency and features of reproductive strategy, longevity, body size, etc. of more than 30 mammalian species. They found that domesticated animal species exhibit higher rates of exchanges than might be expected based on a general relationship among these parameters. The authors attributed this difference to the advantage of increased recombination that facilitated to overcome unwanted correlations between characters in the course of selection. Similar conclusions were achieved in comparative analysis of chiasma frequency of domesticated and wild plant species (Ross-Ibarra, 2004).

At the stage of primitive selection, recombination was a major factor of genetic variation allowing for a deep and very fast (on the evolutionary scale) reorganization of domesticated organisms. Consequently, this selection pressure could become a driving force of evolution of increased recombination, at least during the first phase of domestication (thousands of generations). However, at the second phase, after regular agriculture had become established with more stable environmental conditions, stabilizing selection had to play an ever-increasing role. This might reverse the direction of recombination evolution, at least in some species. For example, Williams *et al.* (1995) established a higher chiasma frequency in primitive forms of maize compared to modern industrial lines.

Polyploid formation is considered a unique evolutionary pathway exploited by both animal and plant organisms. A few of the most important crops, such as wheat, cotton, or potato, are allopolyploids. The recombination-domestication interface may have very interesting aspects when related to polyploids. These include the evolution of diploid-like chromosome behavior in meiotic pairing, recombination and segregation, the effect of various forms of recombination on the coevolution and sequence polymorphism of genomes sharing one nucleus, and the effect of selection on the foregoing processes. Detailed mapping and DNA sequencing efforts on the polyploid crops combined with comparative evidence on their diploid relatives and/or ancestors may be considered an important way of highlighting the role of recombination in evolution and domestication.

Evolutionary Effects of Recombination

Recombination and Genetic Variation for Adaptation to Varying Environment

Producing variation is considered one of the major evolutionary functions of recombination that is supposed to assist in adaptation to both spatial and temporal environmental changes. Abundant genetic variation manifested by natural population is a result of a complex interaction between a few factors: mutation, selection, population subdivision, breeding system, and recombination in its various forms. All other things being equal, genetic variance for a sexual population with free recombination may be several times that for a population with no recombination (Charlesworth, 1993). Classical estimates from *Drosophila* species indicated that up to

25–40% of variation in fitness in natural populations is re-generated by crossing-over in one or two generations from a randomly drawn chromosome pair. Thus, a temporary arrest of the mutation process would not result in a significant decrease in variation over many generations. But does this mean that populations always harbor enough variation to react to external challenges? The author believes that the answer is negative; otherwise, it would not be possible to change recombination by direct selection for quantitative traits unrelated to recombination (*see Experimental Evolution of Recombination*).

An important question is how recombination affects genetic variation. In a population at linkage equilibrium ($LD=0$), changes in recombination rate do not affect the amount of variation. However, this does not mean that the level of variation is independent of r_f . Indeed, the stability of polymorphism varies with r_f . The general trend is a reduction of polymorphism stability with increased recombination. This will occur when one models the dynamics of a diploid population subjected to stabilizing or directional selection with all selected loci linked within a block. Stability of polymorphism for these loci inversely depends on recombination within the block. However, the effect of linkage may be opposite for configurations with multiple blocks of selected loci (Nevo *et al.*, 1997). Another example is selection (either diploid or haploid) in a fluctuating environment (Korol *et al.*, 1996). The effect of recombination on the amount of variation may also result from a dependence of the steady-state LD on r_f : $LD \neq 0$ is achievable (if at all) only at tight linkage and/or strong selection.

Recombination as a Source of Evolutionary Novelties

Through gene duplications (by unequal exchanges), recombination creates prerequisites for increasing variability. In fact, it is a general belief that the evolutionary formation of a new gene by mutation–selection interaction is preceded by the duplication of the genetic material. Local duplications may result from unequal crossing-over, unequal sister chromatid exchange, polymerase slippage, or replicative transposition. Positive association between recombination and copy number variation is well documented for various eukaryotes. There is abundant evidence (from both pro- and eukaryotes) suggesting that structurally (and in many cases functionally) related genes are linked to one another. These may include tandemly repeated gene families, gene clusters (with arbitrary spacing and orientation of the individual genes), and dispersed distribution of the family members across the genome. Different mechanisms were proposed for allele diversification after duplication. For example, a new allele may be produced by intrachromosomal homologous recombination mediated by DNA sequences within the duplicated elements. The creative role of different forms of recombination (unequal crossing-over, gene conversion, reciprocal exchange, and ectopic and illegitimate recombination) is well documented for different organisms.

Recombination was recognized to play an important role in the evolution of gene families that are usually organized in the genome as arrays of tandem repeats residing in one or a few chromosomes. Coordinated change of individual

elements of such families is referred to as concerted evolution. The diversification of the elements by mutations is opposed to homogenization processes caused by unequal crossing-over and gene conversion. This process is opposite to the scenario of evolution of new functions through “recombination (unequal crossing-over) → duplication → diversification (via mutation)”. In the case of multigene families, selection presumably favors the most homogeneous arrays. Different variants of homogenized arrays may coexist within a population, as shown on the rDNA cluster in *Drosophila*. This implies a low recombination between different arrays combined with high intrachromosomal recombination within arrays.

Recombination and Sequence Polymorphism

During the past decades, new evidence became available on the association between recombination and DNA sequence polymorphism in natural populations. The first group of data came from *Drosophila*: Begun and Aquadro (1992) compared variation in *rf* per physical DNA length in different regions of *D. melanogaster* genome with polymorphism of DNA sequences of these regions. Positive correlation between recombination and sequence polymorphism was established. Similar results were obtained in different *Drosophila* species, humans, and some plants. Recombination also seems to play an important role in sequence variation of natural populations for the mitochondrial genome.

Two opposite though not mutually exclusive hypotheses were proposed as explanations for the association between recombination and sequence polymorphism. The first, referred to as selective sweeping, is based on selection of new favorable mutations. In genomic regions with a low recombination rate, the process of fixation of positively selected mutations will result in fixation of closely linked neutral or even slightly deleterious sequence variations. The second explanation is based on the theory of background selection (Nordborg *et al.*, 1996) that considers the consequences of purifying selection against deleterious mutations. This process can also reduce sequence variation at closely linked sequences. Combination of these two mechanisms seems to explain the main pattern of polymorphism–recombination association, although the contribution of additional factors cannot be excluded.

A simple and universal measure of compositional organization of nucleotide sequences is GC content. GC content displays wide interspecific variation as well as high within-genome heterogeneity, especially in mammals, where it is presented in the form of GC isochors. GC content is strongly correlated with biological features of genome organization such as distribution of various classes of repeated elements, gene density, level and tissue-specificity of transcription, and mutation rate. The available data on humans and other organisms point to a strong correlation between GC content and recombination. This connection may be caused by increased recombination in GC-rich regions. An alternative assumption is that recombination machinery is responsible for the evolution of the genomic GC distribution due to the bias of mismatch repair within the gene conversion tracts in favor of GC, which preferentially converts A/T into G/C at sites that are

heterozygous for AT and GC (the biased gene conversion hypothesis). Also, we cannot exclude the possibility that another factor affecting both the evolution of intragenomic heterogeneity in GC content and recombination is responsible for their positive association. An important aspect of the recombination impact on genome organization is related to the amount and distribution of repetitive elements. Amplification of retrotransposons is considered as an important source of repetitive DNA leading to an increase in genome size (“genomic obesity”) in many plant taxa. Recombination was proposed as the mechanism counterbalancing this trend, in particular, unequal crossing-over and intrachromosomal recombination between the repeated elements (Shirasu *et al.*, 2000). Recombination is an important mechanism affecting the formation of microsatellites. Owing to their abundance in the genomes and high variability, microsatellites are considered as accelerators of evolutionary adaptation (Kashi and King, 2006).

Horizontal Gene Transfer

Numerous mechanisms exist that normally prevent the exchange of genetic material among distant species. Nevertheless, if this process is possible even at a low frequency, it may have important consequences on the long-term evolutionary scale. Only 30 years ago, such a possibility was considered an unrealistic one. Now, rich evidence is available showing that the opposite is true. Illegitimate recombination seems to be the main responsible mechanism. Extensive similarities have been revealed between house-keeping genes of Archaea and Eubacteria, although for the majority of informational genes (involved in transcription and translation) the difference is very large. An interesting fact is that some of the foregoing genes showing high similarity between the kingdoms are clustered in the genome that may result from horizontal transfer events.

If horizontal transfer is indeed an evolutionary significant form of genetic recombination, one could consider ecological interaction between species a replacement of sexual interaction (vertical transfer). In other words, ecologically interacting species are the most probable exchanging partners. Viral DNA integration in the host nuclear genome is considered a relatively frequent event (on the evolutionary scale) for animal hosts and recently also for plants. Likewise, there is evidence of an opposite, host → parasite flow of genetic information: Many transfers of signaling domains of pathogenesis-related plant genes were detected in bacterial genomes.

Evolution of Recombination

Theoretical Models of Recombination Evolution

Artificial selection experiments suggest that almost every population has enough stored genetic variability to ensure response to direct selection for changed recombination frequency (*see* Selection for Changed Recombination, Genetic Modifiers of Recombination, and Intraspecific Variation for the Rate of Recombination). The observed polymorphism at loci affecting recombination could be either balanced (selected) or

transient. Theoretical analysis shows that under a stable environment, a panmictic population should evolve toward a minimum possible level of recombination. This can be formulated in terms of the fate of a selectively neutral modifier locus affecting recombination.

Understanding the forces maintaining sex and recombination is considered one of the most challenging problems in evolutionary theory (Michod and Levin, 1988). Shared genetic control and molecular mechanisms of DNA recombination and DNA repair across life (*see* Meiotic Mutants as an Analytical Tool in Recombination Studies: Overlapping of DNA Repair, Recombination, and Segregation Systems and Molecular Mechanisms of Recombination) indicate their common evolutionary origin and functional overlap in extant organisms. It could probably be supposed that repair functions played the leading role at early evolutionary stages, having provided opportunities for a large increase in the genome size and the transition from haploidy to diploidy. The latter offered the possibility of recombination repair of two-strand DNA lesions that is impossible in haploid systems. Some authors hypothesize that the subsequent stages in the evolution of recombination and sex were associated with repair alone. These explanations of repair functions were called “physiological” (Maynard Smith, 1978). Another physiological explanation of recombination in sexuals is its association with chromosome segregation (*see* Meiotic Mutants as an Analytical Tool in Recombination Studies: Overlapping of DNA Repair, Recombination, and Segregation Systems), although numerous examples are known, such as male *Drosophila* and female silkworm, in which normal segregation is associated with achiasmatic (without crossing-over) meiosis.

Combinative, or generative, hypotheses consider the main function of sex and recombination in shuffling genes. This removes negative correlation between favorable alleles at different loci, thereby increasing the efficiency of natural selection. Generative models can be classified according to the source of linkage disequilibria between selected loci: stochastic or deterministic, caused by new mutations or variation of external conditions (Kondrashov, 1993). In the 1930s, Fisher and Muller proposed that sex may be advantageous by combining beneficial mutations randomly occurring in different individuals (Hartfield *et al.*, 2010). A complementary version of the stochastic-mutation explanation considers the role of recombination in selection against deleterious mutations (Muller, 1964). According to Muller, deleterious mutations tend to be fixed in a finite asexual population due to random drift despite purifying selection (Muller’s ratchet), whereas recombination helps to stop this process. In the 1980s, a few deterministic models of selection against deleterious alleles were proposed, with the evolutionary advantage of recombination being dependent on linkage disequilibria resulted from synergistic interaction between harmful mutations produced at a high rate (Kondrashov, 1988). Other models of deterministic sources of linkage disequilibria include (1) adaptation to temporarily or spatially varying environment, (2) antagonistic species interaction (the Red Queen hypothesis), and (3) intraspecific competition (sib competition or tangled bank hypothesis) (Hamilton *et al.*, 1990; Kondrashov, 1993; Korol *et al.*, 1994; Feldman *et al.*, 1997; Barton and Charlesworth, 1998; Otto and Michalakis, 1998). In most of

these models, the conditions favoring increased recombination are associated with negative linkage disequilibria among selected loci owing to stringent conditions for epistasis. Some mechanisms (e.g., selection of beneficial mutations) may favor recombination in the absence of epistasis, with linkage disequilibrium caused by finite population size. The diversity of models proposed to explain the evolution of sex and recombination and their rather complicated “relationships” with the evidence from studies of different organisms, lead to the idea of pluralistic explanation (Michod and Levin, 1988; Korol *et al.*, 1994; West *et al.*, 1999). It suggests that different mechanisms could have played different roles in the emergence, evolution, and, especially, maintenance of recombination and sex in diverse phyletic lines of eukaryotes.

Testing the Theoretical Assumptions

Despite voluminous literature, the problem has been studied little experimentally or by observations in natural populations. In the classical period of genetics, it was proposed that sex and recombination may facilitate selection for advantageous and against deleterious mutations and assist in adaptation to changing environment. The major question is whether these processes in turn are able to promote evolution of the recombination system. Are the resulting changed patterns of recombination detectable experimentally? Is it possible to find corresponding changes in nature? Theoretical models answer positively to these questions. However, do these models (and/or their parameter values) fit the real world? Unfortunately, there is not enough evidence to answer this question. Two different and complementary approaches can be considered (Korol *et al.*, 1994; Barton and Charlesworth, 1998; Korol, 1999).

Testing the Initial Assumptions

The aim is to test whether the real estimates of the main parameters underlying the proposed mechanism(s) fit the expectations. These include mutation rate, effective population size, mode of interaction of deleterious or beneficial mutations, relative role of stabilizing and directional selection, and cost of sex and meiosis. The major advantage of this approach is that it allows the accumulation of data on basic parameters affecting the evolution of recombination. The drawback is that it is difficult to believe that even the main factors were taken into account so that the predicted direction of recombination evolution is determined correctly. As an example of a successful application of this approach, competition experiments with yeast *S. cerevisiae* (Greig *et al.*, 1998) are worth mentioning. Using sexual and asexual strains it was found, contrary to the expectations following from the concept of costs of sex or meiosis, that sex can confer significant selective advantage to its carriers. Direct tests have also been conducted with the nematode *C. elegans* demonstrating the possible role of recombination in purifying selection (Zetka *et al.*, 1987). It was shown that increased *rf* owing to enhancer Rec-1 results in a higher fitness of genotypes carrying mutator gene *mut-6* compared to analogous genotypes with a normal recombination rate. Therefore, the presence of a gene for increased recombination, which presumably has no effect

on mutation, reduces the genetic load caused by the mutator system. However, studies of normal (wild-type) genotypes of *C. elegans* give very low estimates of mutation rate, which is inconsistent with the hypothesis of selection against deleterious mutations.

Searching for Changed Recombination

The second approach is to test the “final effect” by comparing rates and genomic distribution of recombination in experimental and natural populations subjected to contrasted selection regimes during many generations. The advantage of such an analysis is that the target effect (changed pattern of recombination) is estimated directly (see Experimental Evolution of Recombination), although one cannot be sure that it is causally connected only with the presumed process.

Recombination System and Life History Traits

Rasmusson (1927) was possibly the first to discuss the genetic basis of putative differences in recombination systems of outbreeding and inbreeding species. On the basis of extremely high variation in the recombination rate in peas that is usually not found in *Drosophila*, he advanced a hypothesis of possible differences in the system of genetic control of recombination between outbreeders and selfers. In plants, elevated chiasma frequencies were indeed found in selfers compared to related cross-pollinating species (Ross-Ibarra, 2006). The species origin and life conditions determine the strategy for adaptation and hence the “optimum” amount of recombination. Evidence of variation of chiasma frequency in nature and its correlation with ecological and life historical traits is available for different organisms and may be employed to compare alternative theoretical models. In mammals with low reproduction rates, longer life cycles, and small progeny sizes, recombination is higher than in species with short generation times and large progeny sizes (Burt and Bell, 1987), fitting the Red Queen model. Koella (1993) found that in plants with animal-dispersed seeds, recombination is higher than in other plants, and perennials show a higher recombination than annuals when compared among genera but an opposite tendency is displayed on the species level. Similarly, on the whole-genome level, higher cM/Mb ratios were found in trees compared to short-lived herbs and shrubs (Jaramillo-Correa *et al.*, 2010).

The rapidly increasing number of genetically mapped organisms simultaneously demonstrates two opposite patterns. The first is a rather high similarity of some genome-wide characteristics of the recombination system among different species, including the narrow spectrum of the crossover number per chromosome, positive interference, the centromeric effect, and a positive correlation with GC content. The second is the discovery of high variation of recombination features within and between species, with extreme outliers, like honey bees (and other social insects), with their extremely low Mb/cM ratio compared to other insects and some species, for example, *Monodelphis* or *Pinus* and *Hordeum*, with considerably higher cM/Mb compared to correspondingly other vertebrates and plants. In most of the cases, we still do not know the reasons for both, high similarity and high variation.

Especially intriguing is the high stability of number of exchanges per chromosome among higher eukaryotes (4–6 six-fold) despite huge variation of Mb/cM ratio (more than two orders of magnitude – see Table 2).

Experimental Evolution of Recombination

Changes in Recombination Caused by Selection for Adaptive Traits

Theoretical models indicate that directional or variable selection for multilocus traits may promote evolution toward increased recombination if the selected population is polymorphic for recombination-modifying loci (Charlesworth, 1993; Korol *et al.*, 1994; Otto and Barton, 1997). Only a few experiments seem to have a direct bearing on this question. The following are examples with regard to *Drosophila* (Korol, 1999). Clegg *et al.* (1979) attempted to test Fisher's (1930) prediction that stable favorable conditions may promote evolution toward reduced recombination. The experiment started with a large cage population of *D. melanogaster* with maximum LD between allozyme loci of chromosome 3. No general trend in *rf* for 20 generations was revealed, which was explained as an indication of a low epistatic component of selection within the marked interval. Flexon and Rodell (1982) established a synthetic population of *D. melanogaster* and subjected it to selection for DDT resistance for 300 days. By the time of estimation, resistance increased from 10- to 100-fold relative to the control level. The control and treatment populations were compared with respect to recombination rate across the genome. Increased *rf* between marker loci on chromosomes 2 and 3 but not X was found in the selected population. Most experimental studies on recombination evolution have employed one-way selection for fitness traits. The limitation of this scheme is the danger of a change in *rf* caused by initial linkage disequilibria between selected genes and recombination modifiers. Therefore, to assess the effect of selection for geotaxis on recombination in *D. melanogaster*, Korol and Iliadi (1994) employed two-way selection. Forty generations of selection for altered geotaxis resulted in an increment in recombination for the genome of 78 cM for geo+ and 66 cM for geo- lines compared to nonselected control. Selection for negative geotaxis did not affect *rf* in chromosome 2, whereas selection in the opposite direction caused a 4-fold increase in *rf* in the b-cn segment spanning the centromere of chromosome 2. The observed change in *rf*, caused by two-way selection for geotaxis, was attributed to the advantage conferred by selection on recombinants. Similar results were obtained by Rodell *et al.* (2004) in divergent selection for the sternopleural bristle number in *D. melanogaster*. Significantly, increased rates of recombination in chromosomes 2 and 3 were found in both directions of selection, and a tendency for reducing crossover rates was observed in populations subjected to stabilizing selection.

Experimental Evolution of Recombination Caused by Adaptation to Stress

The author reviewed a series of studies with *D. melanogaster* conducted in his laboratory and aimed to demonstrate that population adaptation to adverse conditions may

promote evolution for increased recombination (Korol *et al.*, 1994; Korol, 1999). The experiments were performed on four large heterogeneous populations with the objective of simulating the process of population adaptation to stress and evaluating its effect on recombination. At the start, each population was subdivided randomly into two parts, control (C) and treatment (T); T variants were then subjected to daily fluctuating temperature with amplitude increasing with generations (from 23 to 27 °C at the beginning to 12–32 °C at the end of the experiment). C variants were maintained at 25 °C.

Increased Recombination Resulting from Adaptation to Stressful Conditions

The control and treatment populations appeared to diverge genetically with respect to thermotolerance. Changes in recombination were evaluated using multiple marked lines. All four populations showed one pattern – a segment-specific increase in *rf*, resulting from selection for thermoadaptation. Those that reacted most were the near-centromeric regions of chromosomes 2 and 3 and the left arm of chromosome 3 (Figure 3). The T and C variants were also compared with respect to the frequency of double exchanges (interference). Significant differences in the values of coefficients of coincidence have been found for adjacent and nonadjacent intervals of large autosomes. The general tendency was a reduced interference in T variants, corroborating the results for recombination rate.

Reduction of Recombination Rate under Optimal Stable Conditions

The described divergence over time with respect to recombination rate resulted from two independent trends. An increase in *rf* was observed in populations adapting to adverse conditions, and simultaneously tightening of linkage in control populations that were maintained under optimal temperature. The proportion of these two effects varied in different “treatment–control” pairs corresponding to the structure of the starting population. These results can be considered as the first experimental verification of Fisher’s (1930) hypothesis that in a constant environment selection favors tighter linkage. Indirectly, these results also indicate that

selection against harmful mutations alone seems to be insufficient for maintenance of the normal level of recombination, at least in the genetic material that was tested.

Applied Aspects

Recombination as a Tool of Genetic Mapping

Recombination-based mapping as a method of studying the genetic material topography has been a major analytical approach in genetics for nearly a century. However, until recently this technique was of little applied interest because of a lack of easily scorable markers. The situation changed dramatically with the appearance of DNA markers. Establishing high-quality maps was considered one of the most important objectives in the Human Genome Project, which also included a few model organisms. Mapping efforts allow a better understanding of the organization of genetic material and allow one to conduct far-reaching comparative mapping. This approach is a power tool of ever-increasing importance for studies of genome structure, functioning, and evolution, and for diverse medical and commercial applications of modern genomics. Fine genetic mapping is a basis of positional cloning, an approach proved successful in many organisms. Its efficiency strongly depends on the Mb/cM ratio in the region harboring the target gene. If the target region is very rarely involved in recombination, then map-based cloning is impractical. Induced recombination may be a nontraditional approach for such situations. The availability of dense maps facilitates mapping of genetic disease genes in humans with subsequent cloning, sequencing, and medical applications. An important application of mapping is genetic dissection of complex traits, or quantitative trait loci mapping, especially in the framework of new marker-assisted (or “genomic selection”) strategies in plant and animal breeding.

Recombination as a Major Source of Genetic Variation in Breeding

When viewed at the level of phenotypic traits, genetic innovations produced by recombination on artificial hybridization

Figure 3 Adaptation to daily fluctuating temperature results in a segment-specific increase in recombination rate in large autosomes of *D. melanogaster* (based on data from Korol AB, Preygel IA, and Preygel SI (1994) *Recombination Variability and Evolution*. London: Chapman & Hall).

can arbitrarily be divided into three main types: (1) transgression for individual traits with the range of trait values in the segregating progeny exceeding the respective parental ranges; (2) formation of new trait combinations of the crossed components; and (3) the appearance of new traits (“anomalous” variation) as a result of recombination in genetic complexes with strong nonallelic interactions. These forms of recombination variability play a significant role in breeding programs providing the raw material for selection. The importance of controlling recombination increases with the necessity of involving new genetic resources for breeding purposes, especially in light of ever-decreasing homeostasis and tolerance to abiotic and biotic stresses of elite animal breeds and plant cultivars. New genes are supposed to be introgressed from exotic germplasm based on recombination. This problem is complicated by reduced recombination on distant crosses and linkage drag (close linkage between the target gene and undesirable genes). Hence, manipulating recombination may become an efficient tool of modern breeding.

Recombination and Cancer

There are many aspects of anomalous chromosome and cell behavior and cancer related to DNA metabolism and recombination–repair. A few are noted here.

Mitotic Recombination

A surprisingly large proportion of human neoplasms appear to result from loss of function of tumor-suppressing genes, for example, due to loss of heterozygosity of tumor suppressors. In retinoblastomas caused by loss of heterozygosity, about half of the homozygosity cases appear to be the result of mitotic recombination.

Specificity of Chromosome Translocations

Many types of human cancers are associated with non-homologous recombination events producing specific translocations. This results in an enhanced expression of oncogenes residing in the vicinity of the breakpoint. Some of these oncogenes are transcription factors participating in normal development. It seems reasonable to assume that interaction between recombination and transcription (*see* Recombination Signals, Hotspots of Recombination, and Transcription) may also involve ectopic recombination resulting in the specificity of some tumorigenic translocations (Barr, 1998).

Defects in DNA Repair–Recombination

A few cancer-related genetic disorders of this type have been characterized, including Bloom syndrome, which manifests mutator and hyper-recombination phenotypes; Ataxia telangiectasia mutation, which increases V(D)J-mediated chromosome rearrangement in T lymphocytes; and Omenn syndrome, a disorder caused by mutations of recombination–activation genes Rag1 and Rag2 (related to V(D)J recombination) resulting in severe immune deficiency combined with a complete lack of circulating T and B cells. Recent studies in *Drosophila* and mice show that one of the most important tumor-suppressing genes controlling cell apoptosis, p53, is

also involved in meiotic recombination, suggesting that tumor-suppressive functions may have been co-opted from primordial activities linked to recombination (Lu *et al.*, 2010).

Recombination Shuffling of Genes: New Technologies of Artificial Sequence Optimization

Recombination combined with selection has become the basis for new technologies of “molecular breeding” aimed at improving protein functions via directed evolution *in vitro*. It includes reshuffling of a few copies of the coding DNA by homologous or site-specific recombination with subsequent screening of the resulting sequences for functional (enzymatic) activity. The reshuffling can be provided by template switching in selfpriming polymerase chain reaction (PCR) referred to as sexual PCR. The efficiency of such artificial evolution may be enhanced by increasing the initial genetic variation involved in recombination, for example, by mutagenesis of the target sequences based on error-prone PCR. Another possibility is to include a wider spectrum of parental sequences using the natural diversity of homologous genes of the same or related species or even distant taxa (Crameri *et al.*, 1998). This approach is especially promising for the improvement of molecules that provide resistance against toxic agents or increase survival on minimal media. Experiments including transformation of the engineered sequences into single-cell organisms (*E. coli*) and selection of the transformants showed dozens-to-hundreds- and even thousands-fold increases in efficiency of the target molecules obtained after recombination–selection cycles. DNA shuffling can improve the targeted pathway by complex mechanisms, even though it may be impossible to predict the optimized sequence by a rational design. Of special interest is the use of recombination for engineering novel therapeutic drugs. Namely, homology-independent recombination of human genes with genes from other species may be used for construction of “humanized” proteins (with a part of nonhuman sequence) possessing the desired clinical activity (Griswold *et al.*, 2005). The success of using recombination as a strategy for protein engineering corroborate the findings that recombination causes more tolerable changes in protein coding sequences compared to random mutation, implying a higher importance of recombination as a source of meaningful evolutionary genetic variation (Drummond *et al.*, 2005).

Targeted Gene Replacement

Gene targeting is an experimental approach aimed at producing site-specific changes in the genome based on genetic recombination. Predetermined changes can be introduced in the target site, in both somatic and germline cells. Usually, the targeting system involves a gene mediating site-specific recombination and a specific target locus. The best-known examples are Cre and FLP recombinases (of bacteriophage P1 and yeast) with loxP and FRT targets, respectively. The basic idea is to first transform the target sites flanking a selectable marker into the recipient genome. Subsequent introduction of the recombinase activity leads to the excision

of the marker. Many important applications have been proposed and many others are expected using the powerful strategies of targeted gene replacement. These include controlled expression of transformed genes, disruption of a chosen gene *in vivo* for a better understanding of its role in physiological and pathological processes, disruption of genes to rechannel the biosynthesis and achieve overproduction of certain molecules, site-specific targeting of DNA into embryonic stem cells for production of gene-modified model organisms, targeted delivery of specific constructs aimed at producing antitumor effects or complementing a mutated gene, and testing of gene expression in donor versus recipient tissues in biomedical transplantation studies.

Conclusions

Recombination plays a key role in a remarkably broad spectrum of genetic processes related to DNA repair; sexual reproduction; immunity; genetic diversity; evolution of genes, gene families, chromosomes and the entire genome; and evolutionary adaptation and speciation. Recombination is the basis for traditional breeding, genetic mapping, recombinant DNA technologies and genetic engineering, gene targeting and gene therapy, developmental biology, and cancer genetics. Genetic studies of various organisms have accumulated abundant evidence on common features and peculiarities in genetic control and molecular mechanisms of the main types of genetic recombination, including reciprocal exchange between homologous chromosomes (crossing-over), non-reciprocal exchange (gene conversion), site-specific recombination occurring between homologous sequences, and illegitimate recombination between nonhomologous sequences. However, despite a long history, thousands of studies, and great progress during the last two decades, recombination continues to be a puzzle in the aspects of its mechanisms, evolutionary effects, contribution of biodiversity, and the factors determining its own evolution.

Glossary

Arid A climate lacking in moisture, especially having insufficient rainfall to support many trees or woody plants.

C₃ plant A plant in which CO₂ is first fixed into a compound containing three carbon atoms before entering the Calvin cycle of photosynthesis. Most trees and temperate plants are C₃ plants.

C₄ plant A plant in which CO₂ is first fixed into a compound containing four carbon atoms before entering the Calvin cycle of photosynthesis. Most tropical grasses are C₄ plants.

Mesic A climate with medium moisture supply, neither too dry nor too wet, with sufficient rainfall to support trees and woody plants.

Monsoon A wind system that influences large climatic regions and reverses direction seasonally, bringing with it

heavy rainfall to the region. Most of continental south Asia gets monsoon rains.

Savanna A mixed tree and grass system, with trees ranging from sparse to medium density, with an understory of grasses. Savannas are open, well lit systems. Rainfall usually occurs in the warmer, summer months with a dry period of 2–8 months. Fires are typical across savannas during drier months, and occur at intervals from 1 to 50 years.

Topkill Stem death as a result of fire, although the plant as a whole still survives and can resprout from root-stocks. Seedlings and saplings are particularly vulnerable to topkill.

Tropical dry forest A type of forest found in tropical to sub-tropical regions that has distinct rainy and dry seasons. Many tropical dry forest plants are adapted to withstand high temperatures and seasonal droughts.

Introduction

To most people, the term ‘savanna’ conjures up images of wide expanses of open grasslands, dotted with a few flat crowned trees, and grazed by large herds of roving ungulates (Huntley, 1982). Whilst these images, characteristic of nutrient-rich East African savannas, remain amongst the most enduring in the public consciousness, they fail to capture the diversity of physical, structural, and functional attributes that characterize the different savannas of the world.

The term *savanna* is thought to be derived from a Carib Amerindian word meaning ‘treeless plain’ (Scholes and Walker, 1993; Shorrocks, 2007). It appears to have first been recorded in print in Spanish by G.F. de Oviedo y Valdes (1535) who noted “This name ‘sabana’ is applied to land which is without trees, but with much grass either tall or short” (Bourlière and Hadley, 1970, 1983). Since then, the term has been widely used and variously defined, and extended to include trees (Bourlière and Hadley, 1983). In its currently accepted usage, it refers to systems with a continuous grass layer and a discontinuous stratum of trees (Scholes and Archer, 1997).

Tropical savannas can be more explicitly defined as mixed tree-C₄ grass systems, with an understory predominantly comprised of warm season grasses that utilize the C₄ photosynthetic pathway, while the trees utilize the C₃ pathway (Huntley, 1982; Scholes and Archer, 1997; Sage, 2004; Beerling and Osborne, 2006; Ratnam *et al.*, 2011). C₃ photosynthesis, in which CO₂ is first fixed to produce a three-carbon compound phosphoglyceric acid (PGA), is the more ancestral form, having dominated the process of photosynthetic CO₂ fixation for over 99% of the time since it evolved ~2.7 billion years ago (Osborne and Beerling, 2006). Plants with the C₄

photosynthetic pathway, predominantly grasses, evolved more recently (25–32 Mya (Million years ago)), and have a CO₂-concentrating mechanism based on four-carbon acids, which confers a high photosynthetic efficiency in warm climates and low CO₂ environments (Sage and Kubien, 2003; Sage, 2004; Osborne and Beerling, 2006; Osborne, 2008; Osborne and Freckleton, 2009).

As a biome, tropical savannas are relatively young when compared to other forested biomes of the tropics (Bourlière and Hadley, 1983). Their origin dates back to the late Miocene, ~8–10 Mya, corresponding to the near-synchronous expansion of C₄ grasses around the world, and represents one of the most dramatic examples of biome assembly in the geological record (Beerling and Osborne, 2006; Edwards *et al.*, 2010). The open habitats and newly available food resources associated with expansion of tropical savannas during the Miocene is also linked to the dramatic radiation and assembly of new communities of large herbivores (including horses, rhinos, antelope, and elephants), which evolved to exploit these newly available niches (see Beerling and Osborne, 2006). The spread of savanna ecosystems in Africa is also believed to have played a key role in the evolution of the early ancestors of humans and in the evolution of traits such as bipedalism and dietary adaptations to novel foods (Cerling *et al.*, 2011).

Today, savannas constitute the world’s second largest biome, covering ~33 million km² or nearly 20% of the earth’s land surface (Scholes and Walker, 1993; Ramankutty and Foley, 1999; Beerling and Osborne, 2006). They are widespread across Africa, Asia, South America, and Australia, and cover more than half the area of the southern continents. They support a fifth of the world’s human population and a majority of its rangeland and livestock biomass (Scholes and

Archer, 1997). They are also home to some of the greatest diversity and densities of wild herbivores and carnivores of any ecosystem on earth.

Distribution of Savannas

Biogeographers have traditionally mapped the occurrence and distribution of biomes across the globe as a function of temperature and precipitation (e.g., Whittaker, 1975; **Figure 1**). In these frameworks, savannas occur between deserts and tropical dry forests, but the transitions between grassland, savanna, and woodland have not been easy to classify (**Figure 1**). This reflects a long standing unresolved issue in the understanding of the savanna biome. The limits to its distribution and the nature of the biome boundaries at both the arid and the mesic end are highly variable across the globe, and the dynamics underlying these patterns remain poorly understood. Many landscapes in the mesic end of the savanna biome, for example southern peninsular India, mainland Southeast Asia from Myanmar through northern Thailand, and the Guinean and Congolian savanna-forest regions in Africa are characterized by a dynamic mosaic of vegetation with open savannas, woodland savannas, and tropical dry forests occurring in a patchwork within the same climatic envelope (White, 1983; Stott, 1991; Ratnam *et al.*, 2011). Climate alone thus appears insufficient to explain the distribution of the savanna biome (Bond, 2008; Hirota *et al.*, 2011; Staver *et al.*, 2011). Further, the physiognomy of anthropogenic savannas is very often similar to that of natural ones, further complicating efforts to map the 'natural' occurrence of savannas (Bourlière and Hadley, 1970).

Tropical savannas dominated by C_4 grasses are extensive and largely occur in a latitudinal band $\sim 30^\circ$ N and S of the equator (**Figure 2**, Bond, 2008; Edwards *et al.*, 2010).

Figure 2 Global distribution of savannas and grasslands. Orange regions are systems where C_4 grasses predominate, while systems where C_3 grasses dominate are shown in yellow. Forests (green), croplands (red), and desert and ice-covered regions (beige-green) are also shown. The dots indicate regions where the geological history of C_4 grasses has been well described. They occupy sites across a range of soil types and rainfall regimes (Huntley, 1982; Shorrocks, 2007). All savannas are characterized by a distinct dry season that ranges anywhere from 2 to 9 months of the year, and during which fires are a typical phenomenon (Schimper, 1903; Sarmiento, 1984; Stott, 1988; Scholes and Walker, 1993; Lloyd *et al.*, 2008). With this caveat, depending on the continent, rainfall in the wet season can range from 200 to 2500 mm (Nix, 1983; Stott, 1988; Lehmann *et al.*, 2011; Staver *et al.*, 2011).

Across their range of occurrence, savannas are extremely variable in their physical and structural attributes. They encompass a gradient from nearly pure grasslands to closed woodlands (Figure 3), exhibit differences in the characteristics of dominant trees (fine-leaved vs. broad-leaved), herbaceous vegetation (tall vs. short grasses, vegetated vs. bare patches), plant life-history characteristics (deciduous vs. evergreen trees, annual vs. perennial grasses), tree spatial patterns (random, regular, or clumped) and plant and soil nutrient status (nutrient-poor or dystrophic savannas vs. nutrient-rich or eutrophic savannas; House *et al.*, 2003; Sankaran and Anderson, 2009).

This inherent variability in savannas across their distributional range can pose problems when it comes to characterizing and mapping savannas, and developing a synthetic understanding of their functioning. As Lamotte and Bourlière (1983) noted: "... there is no such thing as a 'typical' savanna

ecosystem. Rather, there is a gradient of related ecosystems ranging from open woodlands to almost treeless 'steppes'. However, these systems all share a number of common features which make them similar to each other rather than different". In the following sections, we focus on the commonalities of these systems in terms of the different driver variables, the interactions amongst which lead to the observed variability in their structure, composition, and functioning.

Drivers of Savanna Structure and Function

Savannas are ecologically unique in featuring the coexistence of two contrasting plant life-forms – trees and grasses – that share resources to a meaningful degree. How these two contrasting life-forms coexist without one displacing the other has been the subject of much research, and has been termed the 'savanna question' (Sarmiento, 1984). Traditionally, four key variables have been identified as being critical to determining savanna structure: water, nutrients, fire, and herbivory (Frost *et al.*, 1986). However, ecologists have been polarized in their views on the relative roles of 'bottom-up' forces (water, soil nutrients) versus 'top-down' forces (fire and herbivory) in fostering coexistence of both life-forms and determining the relative balance of trees and grasses in savannas.

Bottom-Up Control of Savannas

In the 'bottom-up' view, tree-grass coexistence and relative abundance in savannas is largely determined by the differential abilities of these two life-forms to partition and acquire limiting resources (Walter, 1971; Walker *et al.*, 1981; Walker and Noy-Meir, 1982; Scholes and Archer, 1997; van Langevelde *et al.*, 2003). Coexistence arises from spatial and/or temporal niche differences between trees and grasses in the acquisition of limiting resources, primarily water. The classic 'bottom-up' model of savannas is the root niche separation model (Walter, 1971). Here, spatial differences in rooting profiles allow trees and grasses to coexist by differentially exploiting soil water. Shallow-rooted grasses exploit only the upper layers of the soil profile, whereas deep-rooted trees are able to additionally access water from lower down in the soil profile. In this view, a characteristic tree-grass ratio is expected for a given set of rainfall and soil conditions, with tree cover increasing as one moves from arid to mesic sites. As rainfall increases across this gradient, more water percolates to depths, increasingly favoring trees over grasses. However, factors that alter the ratio of subsoil to topsoil water (e.g., variable rainfall patterns, grazing) can cause realized tree-grass ratios to deviate from this predicted ratio (Walker and Noy-Meir, 1982; van Langevelde *et al.*, 2003).

Temporal niche separation by phenology has also been proposed as a mechanism potentially contributing to tree-grass coexistence in savannas (Scholes and Archer, 1997; House *et al.*, 2003). The ability to store water and nutrients allows savanna trees to flush leaves and achieve full leaf expansion prior to, or shortly after the onset of the rains, while grasses only achieve their peak leaf area later in the growing season (Scholes and Archer, 1997). Savanna trees also typically retain their leaves for weeks following grass senescence (Scholes and Archer, 1997). Even though grasses are believed to be the better competitors for soil water during periods of growth overlap, exclusive access to soil water early and late in the growing season allows trees to persist in the system (Scholes and Archer, 1997; Sankaran *et al.*, 2004).

Most models of 'bottom-up' controls in savannas have focused on niche partitioning with respect to water rather than nutrients (Walter, 1971; Walker *et al.*, 1981; Walker and Noy-Meir, 1982; van Langevelde *et al.*, 2003). Since nutrient uptake is tightly coupled to water uptake, the models previously described are also applicable to the case of a single nutrient limiting both tree and grass growth. However, coexistence can also theoretically arise if trees and grasses are limited by, and have differential abilities to acquire, different nutrients.

In the 'bottom-up' perspective, savannas are viewed as 'stable' systems to the extent that disturbances such as fire and grazing, although capable of shifting the balance between trees and grasses, are not prerequisites for the persistence of both life-forms in the system.

Top Down Control of Savannas

The 'top-down' view represents a departure from traditional equilibrium models of savannas in that the emphasis is on demographic, rather than physiological mechanisms (Higgins

et al., 2000; van Wijk and Rodriguez-Iturbe, 2002; Sankaran *et al.*, 2004). Here, primacy is given to the roles of disturbances such as herbivory and fire in regulating savanna structure. Both fire and grazing act to regulate tree cover in savannas by imposing demographic bottlenecks, or in some cases eliminating bottlenecks, to tree recruitment and establishment (Higgins *et al.*, 2000; Sankaran *et al.*, 2004; Bond, 2008). The nature of the bottleneck can vary depending on the environment (Higgins *et al.*, 2000; Bond, 2008). In arid savannas, the primary bottleneck for trees is at the germination and seedling establishment stage (Jeltsch *et al.*, 1998; Higgins *et al.*, 2000; van Wijk and Rodriguez-Iturbe, 2002). Localized deposition of tree seeds in herbivore dung can provide more suitable conditions for tree seedling germination and establishment, thus eliminating the bottleneck and allowing trees to persist in the system (Jeltsch *et al.*, 1998). Similarly, grazing can reduce grass competition and favor tree establishment in areas where seedlings might otherwise have been outcompeted by grasses (Sankaran *et al.*, 2004). In contrast, in more mesic sites, disturbances such as fire and browsing serve to impose bottlenecks on seedling establishment and transition to adulthood. Frequent fires 'topkill' saplings, and result in direct mortality or force saplings to resprout from rootstocks (Higgins *et al.*, 2000). Adult savanna trees, however, are fairly immune to the effects of grass-fueled fires (Higgins *et al.*, 2000; Bond, 2008). Saplings only escape the 'fire trap' and transition into adult size classes when the interval between successive fires is long enough to allow them to grow above the flame zone (Higgins *et al.*, 2000). Browsers can similarly impose bottlenecks on tree establishment either directly as a result of browsing-induced mortality of seedlings, or indirectly, by slowing down seedling growth rates and thus maintaining them within the 'fire trap' (Sankaran *et al.*, 2004).

In the top-down view, savannas are essentially considered to be 'unstable' systems. Pure forests and grasslands are presumed to be the only stable states, and disturbances such as fire and grazing permit savannas to exist by 'buffering' the system against transitions to either extreme (Jeltsch *et al.*, 1996, 1998, 2000; Higgins *et al.*, 2000). Savannas exist because of factors that favor tree establishment at the arid end of the rainfall gradient, and factors that prevent canopy closure at the mesic end.

Limits to Woody Vegetation in Savannas

The importance of bottom-up (water, nutrients) and top-down forces (fire, herbivory) for savanna structure has been long recognized (Sarmiento, 1984; Frost *et al.*, 1986; Scholes and Archer, 1997; Stott, 1991), but their relative importance has also long been debated (Scholes and Archer, 1997; Bond *et al.*, 2003; Sankaran *et al.*, 2004; Bond, 2008). In an effort to resolve these issues, ecologists have recently begun to synthesize data across large environmental gradients in an attempt to gain a more comprehensive understanding of savanna woody community dynamics (Bond *et al.*, 2003; Sankaran *et al.*, 2005; Bucini and Hanan, 2007; Good and Caylor, 2011). Much of this synthesis has centered on African savannas, with very little from Asia, and as a result our knowledge of the dynamics of Asian savannas is rather limited.

For Africa, water availability has been identified as a critical determinant of savanna structure, setting limits to the maximum tree cover that can be supported in sites (Figure 4(a), Sankaran *et al.*, 2005). Analysis of data from over 850 savanna

Figure 4 (a) Maximum tree cover in Africa's arid savannas (<650 mm MAP) is limited by water availability, while water availability in mesic savannas (>650 mm MAP) appears sufficient to support a closed canopy. The upper bound on tree cover was fitted using a 99th quantile piecewise linear regression model. The breakpoint, that is, rainfall at which maximum tree cover is attained lies in the interval 650 ± 134 mm MAP. Data are from 854 sites across Africa (Reproduced from Sankaran M, Hanan NP, Scholes RJ, *et al.* (2005) Determinants of woody cover in African Savannas. *Nature* 438: 846–849). (b) Effects of wet season rainfall depth (α_w) on woody cover in African savannas. The dark line represents the maximum potential woody cover that can be supported in sites with less intense rainfall events (mean rainfall depth $\alpha_w = 5 \pm 1$ mm; x symbols), and the gray line for sites with more intense rainfall events ($\alpha_w = 15 \pm 1$ mm; o symbols). Sites with less frequent but more intense rainfall events support lower tree cover than sites with more frequent but less intense events. Tree cover data are derived from MODIS and precipitation data from TRMM (Reproduced from Good SP and Caylor KK (2011) Climatological determinants of woody cover in Africa. *Proceedings of the National Academy of Sciences* 108: 4902–4907).

sites distributed across the African continent reveals an upper bound on maximum potential tree cover in arid and semiarid savannas that receive between ~ 150 and 650 mm rainfall annually (Figure 4(a), Sankaran *et al.*, 2005). Within this rainfall range, maximum potential tree cover that can be supported in sites increases linearly with annual rainfall (Figure 4(a)), but appears unrelated to fire frequency, herbivory, or soil properties (Sankaran *et al.*, 2005). Above the 650 mm threshold, mean annual rainfall appears sufficient to allow for a closed woody canopy, such that disturbances like fire and herbivory become critical for the persistence of both trees and grasses in the more mesic savannas (Bond *et al.*, 2003; Sankaran *et al.*, 2005). The importance of mean annual rainfall in setting limits to tree cover that can be supported in arid and semiarid savannas has also been documented in other continental scale analyses based on remotely sensed estimates of tree cover in African savannas (Bucini and Hanan, 2007; Good and Caylor, 2011; Greve *et al.*, 2011).

Besides total rainfall, rainfall seasonality has also been shown to play an important role in determining tree cover in sites (Figure 4(b), Good and Caylor, 2011). Good and Caylor (2011) demonstrated that for areas with similar seasonal rainfall amounts, sites characterized by frequent, less intense precipitation events tended to have higher tree cover than sites with less frequent, but more intense precipitation events. When precipitation events are intense, more water runs off as surface flow and less percolates into soils, reducing water availability and lowering tree cover compared to sites where rainfall events are less intense.

In other recent work examining the limits of savanna occurrence across the southern continents, Lehmann *et al.* (2011) also highlight the importance of rainfall seasonality as a predictor of savanna occurrence in any given landscape. The authors suggest a mechanistic explanation for the same: rainfall seasonality is important because it simultaneously decreases rates of woody canopy closure (Sarmiento, 1984; Good and Caylor, 2011) and increases the probabilities of disturbances such as fire that open up woody canopies (Archibald *et al.*, 2009). The counter-balance between these two processes is critical to maintain the open state that characterizes savannas.

Although the existence of an upper bound on tree cover in arid and semiarid savannas is consistent with the predictions of 'bottom-up' or niche-based models of tree–grass coexistence (Walker *et al.*, 1981; Walker and Noy-Meir, 1982), the actual mechanisms underlying the observed pattern remain unclear. For one, Walter's root niche separation hypothesis (Walter, 1971), which is the mainstay of 'bottom-up' models, is not empirically supported in many savannas (Scholes and Archer, 1997; Higgins *et al.*, 2000; Sankaran *et al.*, 2004; Bond, 2008; Kulmatiski *et al.*, 2010). Root-niche separation models also do not consider the seedling stages of trees when there is no spatial separation of roots and seedlings compete directly with grasses for soil resources (Sankaran *et al.*, 2004; Bond, 2008). This, combined with the lack of empirical support, has led many authors to conclude that the root-niche separation model is not 'tenable' as a general explanation for the observed tree cover patterns in savannas (Bond, 2008). The role of phenological differences between trees and grasses in generating the observed bound on maximum tree cover in arid

and semiarid savannas is similarly unclear. Thus, while it is clear that resource availability, particularly water, plays a critical role in defining the maximum potential tree cover that can be supported at any site, the specific mechanisms generating the observed pattern remain unclear.

Factors Regulating Savanna Structure

The observed variability in tree cover across rainfall gradients in African savannas (Figure 4) suggests that maximum woody cover is rarely realized, with tree cover in most savannas well below the 'climatic' potential (Bond *et al.*, 2003; Bond, 2008; Sankaran *et al.*, 2008). Clearly, other processes besides water availability play a role in defining patterns of realized or observed tree cover in savannas. Analysis of observed tree cover data from a range of sites across Africa indicates that after water availability, fires accounted for much of the observed variation in tree cover, followed by soil properties and herbivory (Sankaran *et al.*, 2008). Similar analyses have not been conducted for Asian savannas; in fact, Asian savannas have been singularly omitted in many texts and large scale syntheses of savanna dynamics (Huntley and Walker, 1982; Lehmann *et al.*, 2011; Hirota *et al.*, 2011; Staver *et al.*, 2011). However, it is likely that all of these factors are just as important, even if to varying degrees, in regulating savanna structure in Asia.

Fire

Fires are well recognized as a major driver of savanna structure (Higgins *et al.*, 2000; Bond *et al.*, 2003, 2005; Bond, 2008). Savanna fires are typically surface fires, fueled by grasses, and rarely spread to tree canopies or kill adult trees (Higgins *et al.*, 2000; Bond, 2008). Their effects on savanna structure largely arise through the bottlenecks they impose on seedling and sapling survival and growth, with the extent and severity of the bottleneck varying depending on fire season, frequency, and intensity (Higgins *et al.*, 2000; Bond, 2008; Midgley *et al.*, 2010). Fires topkill saplings and force them to resprout to survive, thus 'trapping' them within the grass flame zone, or 'fire trap' (Higgins *et al.*, 2000). Fire impacts on regrowth and survival are highly dependent on size and species (Gignoux *et al.*, 1997; Mistry, 2000; Hoffmann and Solbrig, 2003; Midgley *et al.*, 2010). Within a species, larger saplings typically tend to survive better (Hoffmann and Solbrig, 2003; Bond, 2008), while across species growth and survival in the face of frequent fires can vary depending on factors such as bark thickness and bark moisture content (Gignoux *et al.*, 1997; Midgley *et al.*, 2010). For example, tree species characteristic of forests tend to have thinner barks than savanna species and are less fire tolerant than savanna species (Hegde *et al.*, 1998; Hoffmann *et al.*, 2009). Further, the ability of savanna tree saplings to 'juggle carbon' between growth, maintenance, and storage, such that root reserves are replenished before the next fire event, is probably a key factor allowing many savanna species to persist indefinitely within the flame zone (Schutz *et al.*, 2009; Wigley *et al.*, 2009). In *Acacia karroo*, root starch reserves can be replenished, and match those of unburned saplings, within a year following topkill; thus allowing it to survive in the face of very frequent fires (Schutz *et al.*, 2009).

Species that lack the ability to replenish root reserves quickly are unlikely to persist in fire-prone environments. Fires thus act as a filter selecting for species with fire-adapted traits and are not only regulators of savanna structure, but also of its composition.

Besides modifying woody vegetation structure where they occur, fires also serve to extend the distribution of savannas beyond their climatically determined limits (Bond *et al.*, 2005). Bond *et al.* (2005) used dynamic global vegetation models (DGVMs) to compare potential and realized vegetation in a world with and without fire. Models that included fire better predicted current global vegetation distributions when compared to models in which fire had been 'switched off', particularly for systems dominated by C_4 grasses (Figure 5, Bond *et al.*, 2005; Bond, 2008). The models suggest that in the absence of fire, forests would nearly double their current extent, occupying regions that presently support savanna vegetation, both in Africa and Asia (Figure 5, Bond *et al.*, 2005).

Long-term fire exclusion experiments have similarly shown that fire is a critical factor for savanna trees and provides unequivocal evidence that tree biomass and species composition in many savannas, particularly the more mesic ones, are not at equilibrium with climate and resources, but rather depend on fire regimes (Bond *et al.*, 2003; Bond, 2008). Large scale analyses indicate that in many areas of the globe which are characterized by intermediate rainfall (1000–2500 mm annually) and mild seasonality (dry season <7 months), tree cover is bimodal, with both forest and savanna co-occurring within the same climatic envelope (Wilson and Agnew, 1992; Hirota *et al.*, 2011; Staver *et al.*, 2011). Forests and savannas here may represent alternate states differentiated by, and maintained through, fire feedbacks (Wilson and Agnew, 1992; Staver *et al.*, 2011). Frequent fire maintains open canopies with fire-tolerant C_4 grasses in the understory, which in turn promote fires and the savanna state in a positive feedback loop. Above a certain threshold of tree cover, shade-intolerant C_4 grasses are excluded from the system, reducing both fuel loads and fuel contiguity, inhibiting fires and maintaining the system in a forested state (Staver *et al.*, 2011).

Nutrients

Soil properties, including texture and the availability of mineral nutrients such as nitrogen (N) and phosphorus (P), also play an important role in regulating savanna structure (Scholes and Archer, 1997; Sankaran *et al.*, 2008). Tree cover tends to be higher in savannas on coarse-textured sandy soils compared to those on fine-textured clay soils (Williams *et al.*, 1996). Sandy soils allow for greater water percolation to depths, thus favoring deeper rooted woody vegetation (Walker and Noy-Meir, 1982). Tree cover across a range of African savanna sites has also been shown to have a strong negative dependence on soil N availability, with tree cover typically lower in N-rich sites (Sankaran *et al.*, 2008). Tree seedling survival and growth have been shown to decrease with increases in soil N, both directly due to the preemption of N by herbaceous vegetation, as well as indirectly as a result of faster depletion of soil water following the stimulation of herbaceous growth (Davis *et al.*, 1999; Kraaij and Ward, 2006; van der Waal *et al.*, 2009, 2011; Cramer *et al.*, 2010).

Figure 5 A comparison of (a) biome distributions simulated by a DGVM with fire switched off, and (b) actual vegetation distribution. The map of actual vegetation was sourced from ISLSCP (http://daac.gsfc.nasa.gov/data/inter_disc/biosphere/land_cover/). Biomes are characterized by the dominant plant functional types: C₃ grasses or shrubs, C₄ grasses, Angiosperm trees (Ang), Gymnosperm trees mainly conifers (Gym). Croplands and bare ground (deserts, ice) are also shown. The numbers indicate locations of long-term field experiments of fire suppression (see Bond *et al.*, 2005; Bond and Keeley, 2005). The simulations indicate that high rainfall sites show a successional tendency toward forests in the absence of fire, suggesting that large areas of the globe are not at their climatic potential as a result of fires. Reproduced from Bond WJ, Woodward FI, and Midgley GF (2005) The global distribution of ecosystems in a world without fire. *New Phytologist* 165: 525–538, with permission from Wiley.

van der Waal *et al.* (2009) have shown that the negative effects of increased N availability on tree seedling growth and survival can be exacerbated during droughts, suggesting that the effects of soil N availability on tree–grass competition is likely to vary across rainfall gradients, with suppression of seedling growth by grasses more pronounced in arid, fertile areas compared to mesic, fertile areas.

Soil P availability has also been shown to be an important predictor of tree cover in a pan-African dataset, more so than soil N (Sankaran *et al.*, 2008). However, although total soil P explained a significant fraction of the observed variability in tree cover in this study, the nature of the relationship between total soil P and tree cover is complex and nonlinear (Sankaran *et al.*, 2008), potentially reflecting the fact that total soil P is not necessarily a good indicator of plant available P

(Cramer *et al.*, 2010). Few studies have explicitly considered the effects of P availability on tree–grass competition, but available evidence suggests that, contrary to N availability, grass suppression of seedling growth may be greater in P deficient soils compared to P-rich soils (Cramer *et al.*, 2010). The reasons underlying these differential responses are unclear, and our understanding of the role of P availability in regulating savanna vegetation dynamics remains far from complete.

Although soil properties can have substantial impacts on tree cover and tree–grass interactions at local scales (White, 1983; Williams *et al.*, 1996; Staver *et al.*, 2011), the extent to which nutrient availability limits savanna distribution is unclear. Low nutrient availability has often been cited as a reason for the occurrence of savannas in areas with sufficient rainfall to support forests. For example, vegetation ecologists working

in the mesic savanna regions of mainland southeast Asia that receive between 800 and 2000 mm rainfall annually, have noted that open savanna formations tend to be associated with low nutrient edaphic conditions such as coarse sandy soils or rocky hill slopes (Puri, 1960; Champion and Seth, 1968; Blasco, 1983; Stott, 1984, 1990). However, Bond (2010), based on a nutrient-stock analysis of forests and savannas, concluded that low nutrient availability seldom constrains forest development. Rather than nutrient availability alone, its interactions with other factors such as fire and herbivory may be critical for explaining vegetation structure (Bond, 2010). In agreement with this, Lehmann *et al.* (2011) noted that soil fertility has contrasting associations with the occurrence of savannas at the arid and mesic ends of the biome. In arid regions, sites with high soil fertility support savannas, while the opposite is true for mesic regions where sites of low soil fertility are more likely to support savannas. The mechanisms underlying these effects are probably different. It is likely that fertile sites in arid regions attract herbivores which then play an important role in reducing grass cover and allowing trees to establish (Fritz and Duncan, 1994; Asner *et al.*, 2009; Staver *et al.*, 2009). In contrast, in sites with low soil fertility in mesic regions, slow rates of woody growth and canopy closure between successive fires might prevent the system from reaching a forested state that rainfall might otherwise support.

Herbivores

The importance of large mammalian herbivores for African savannas is well recognized (Scholes and Archer, 1997). Unfortunately, little is known about the impacts of native herbivores on savanna structure in Asia (Mistry, 2000). This lacuna is somewhat surprising given that Asia supports the highest richness and biomass of mammalian herbivores of any continent outside of Africa, including mega-herbivores like elephant and rhinoceros. Nevertheless, given the similarities in the herbivore assemblages between the two continents, lessons learnt from Africa are likely to be broadly applicable to Asian savannas.

The effect of mammalian herbivores on savanna vegetation is contingent on population densities and body size, and varies depending on whether the species is a browser, mixed feeder, or grazer (Augustine and McNaughton, 1998, 2004; Sankaran *et al.*, 2008). Mega-herbivores – those with a body mass > 1000 kg – such as elephants, often tend to have a disproportionate effect on savanna woody vegetation and are capable of radically transforming savanna landscapes (Guldemand and van Aarde, 2008). In general, elephants tend to have a negative effect on woody vegetation, reducing tree cover and ‘opening up’ savannas (Sankaran *et al.*, 2008), with the magnitude of such effects varying with elephant densities and rainfall (Guldemand and van Aarde, 2008). Browsers and mixed-feeders, similarly, have negative effects on woody vegetation structure that arise from both their direct and indirect effects on tree recruitment (van Langevelde *et al.*, 2003; Augustine and McNaughton, 2004). Selective browsers can significantly depress growth rates and increase mortality of shrub seedlings and saplings, thus imposing strong bottlenecks to tree and shrub recruitment (Augustine and McNaughton, 2004). Browsers and mixed-feeders can also

limit tree establishment indirectly in more mesic and fire-prone environments by reducing growth rates and maintaining seedlings and saplings within the flame zone; thus rendering them more prone to topkill from fires (Scholes and Archer, 1997; Sankaran *et al.*, 2008). Browsing on seedlings late in the growing season can also limit their ability to replenish carbohydrate reserves in root-stocks and reduce their resprouting vigor, making them more susceptible to mortality from subsequent fires (Schutz *et al.*, 2009; Wigley *et al.*, 2009). Large scale documented increases in tree cover accompanying the loss or reduction of browser populations following disease outbreaks like rinderpest are testimony to the impact of browsers on woody vegetation dynamics in savannas (Prins and van der Juegd, 1993).

Grazer effects on woody vegetation are more complex, with grazers having both positive and negative effects across gradients of grazing intensity (Sankaran *et al.*, 2008). For example, relief from grazing has been associated with increases in woody cover (Lenzi-grillini *et al.*, 1996). Similarly, overgrazing has also been implicated as a causal agent for shrub encroachment in grazing lands worldwide (Archer, 1995; Scholes and Archer, 1997; Roques *et al.*, 2001; Eldridge *et al.*, 2011). Enhanced woody cover under sustained grazing can result from multiple factors including (1) reduced competition from grazed grasses, (2) increased water availability for deeper rooted shrubs as a result of lowered uptake by grazed grasses, (3) reduced fire frequencies and intensities due to lower grass fuel loads, and (4) dispersal of woody seeds by grazers (Brown and Archer, 1987; Archer, 1995; Scholes and Archer, 1997; Roques *et al.*, 2001; Eldridge *et al.*, 2011). Further, grazers, particularly cattle, have also been shown to indirectly facilitate shrub recruitment by suppressing populations of seed and seedling predators, primarily rodents (Goheen *et al.*, 2010).

Classification of Savannas

Reflecting the above variability in the drivers and structural properties of savannas, scholars have classified savannas using a number of different criteria, depending upon the question of interest. In the following two sections, we describe the most widely used classifications of African and Asian savannas in some detail.

African Savannas

African savannas are probably the most well-researched savanna ecosystems in the globe, and consequently we have a very good idea of their distribution and vegetation. African savannas have either been distinguished based on their climatic and edaphic ranges, their physiognomy and structure, or the functional attributes of the dominant life-forms. These different systems are not always mutually exclusive and the descriptors are often used interchangeably by different sources in the literature.

Arid, Eutrophic Versus Mesic, Dystrophic Savannas

This classification highlights important differences in the water and nutrient status of savannas, which tend to covary at

the continental level in Africa (Huntley, 1982; White, 1983, **Figure 6(a)**). Savannas that occur on the more ancient surfaces of the African shield tend to be wetter and relatively nutrient poor ('dystrophic') while those that occur on the more 'recent' surfaces formed since the breakup of Gondwanaland tend to be drier and more fertile or 'eutrophic'

(Scholes and Walker, 1993). This covariance at the continental scale results from the fact that nutrient leaching on the older, wetter sites has been more pronounced and prolonged than on the drier, younger surfaces on the continent, which also happen to occur on more nutrient-rich parent material (Scholes and Walker, 1993).

Figure 6 Distribution of (a) arid, eutrophic (black) and mesic, dystrophic (dark gray) savannas (map derived from White F (1983) *The vegetation of Africa*. Paris: UNESCO by combining different vegetation classes); and (b) savannas with different life-form associations across Africa. Reproduced from Shorrocks B (2007) *The Biology of African Savannas*. Oxford: Oxford University Press.

Broadly, arid, eutrophic savannas typically receive <650 mm Mean Annual Precipitation (MAP) and occur on calcareous and eutrophic noncalcareous soils (exchangeable bases >15 me/100 g clay; Huntley (1982)). Most of these savannas experience seven or more months of mid-summer droughts. Where they extend into subtropical areas, frost tends to be a regular phenomenon in arid savannas. Moist or humid savannas occur in areas that receive >650 mm MAP annually, and on dystrophic and mesotrophic noncalcareous soils (exchangeable bases <15 me/100 g clay; Huntley (1982)). Mid-summer drought is also a feature of these savanna types at the lower limit of their moisture range. Frost is generally absent over most of the range of moist savannas.

Despite the rather coarse-grained scale of such a classification, it has nevertheless proved quite useful for continental scale analyses of African savannas. In particular, the distribution and abundance of large mammalian herbivores in Africa is predictable to a large degree based on this functional classification, highlighting the importance of water and nutrients for savanna structure and function (Scholes and Walker, 1993).

Savannas With Different Life-Form Associations

Several authors have classified savanna types in Africa based on the dominant life-forms and structural attributes of these systems. Even while these classes are based on the appearance of the vegetation, they nevertheless convey a sense of the climatic zone in which a system occurs because vegetation structure is often associated in predictable ways with temperature, soil fertility, and rainfall. Here, we follow the classification scheme and descriptions developed by Shorrocks (2007) and simplified from White (1983), which combines elements of vegetation structure with information on species associations (Figure 6(b)). It is important to recognize that while such schemes differentiate savanna types at a continental scale, they fail to capture the inherent heterogeneity that characterizes savannas at regional or local scales.

Grass and Shrub Savannas

Familiar to most as the 'Sahelian' savanna in northern Africa, these arid savannas occupy the transition zone between the Sahara Desert in the north and the more humid savannas in the south, stretching from Senegal and Mauritania in the west to Sudan in the east. In the drier west (100–600 mm mean annual rainfall), the woody component is dominated by shrubby forms of *Acacia laeta*, *Acacia tortilis*, and *Balanites aegyptiaca* while the grass cover is dominated by annual species such *Cenchrus biflorus*, *Schoenefeldia gracilis* and *Aristida stipoides*. Where these savannas reach the horn of Africa, they merge into *Acacia–Commiphora* associations, which stretch east of the Ethiopian highlands and down into the Maasai drylands of Tanzania and southern Kenya. Here, where rainfall is bimodal and higher (600–800 mm mean annual rainfall), perennial grasses such as *Themeda triandra*, *Panicum coloratum*, *Aristida adscensionis*, and *Andropogon* and *Eragrostis* species dominate the grass community.

In southern Africa, these 'grass and shrub' formations form the transition between the southern deserts and northern mopane savanna. Mean annual rainfall ranges from 200 to 500 mm. In the northern part of this region, dense short

savannas are characterized by the presence of species with succulent stems such as *Aloe dichotoma*, *Euphorbia guerichiana*, and *Moringa ovalifolia* predominately. Toward the south, the vegetation becomes more open and is dominated by karoo shrubs such as *Parkinsonia africana*, *Acacia newbournii*, and *Boscia* species. Tufted grasses, mainly of the genus *Stipagrostis*, are found scattered in the understory.

Tree and Shrub Savanna

These savannas, which are more mesic than the 'grass and shrub' savannas above, occur in the regions immediately north and south of the rainforests and miombo woodlands of central Africa. In the northern section, mean annual rainfall ranges from 600 to 1000 mm and the climate is strongly tropical. The woody component is dominated by species of *Combretum* and *Terminalia*, with other common species being *Anogeissus leiocarpus*, *Boswellia papyrifera*, *Balanites aegyptiaca*, *Stereospermum kunthianum*, *Commiphora africana*, *Prosopis africana*, and *Ziziphus mucronata*. Tall grasses such as *Pennisetum purpureum* (elephant grass) and species of *Hyparrhenia*, *Cymbopogon*, and *Echinochloa* dominate the grassy layer.

South of the miombo woodlands of Central Africa, 'tree and shrub' savannas are characterized by the dominance of the mopane tree *Colophospermum mopane*, with its distinctive butterfly-shaped leaves and dense clonal stands. In the southeastern 'Zambezian' region, mean annual rainfall ranges from 450 to 700 mm, but some regions may receive as much as 1000 mm of rain. Here, the mopane tree shows great variation in its structural form, ranging from stunted 1–3 m bushes to 25 m tall trees depending on local soil conditions, with the two structural forms often occurring in a mosaic across the landscape (White, 1983). While mopane is dominant, other trees that occur in these formations include *Kirkia acuminata*, *Dalbergia melanoxylon*, *Adansonia digitata*, and species of *Combretum*, *Acacia*, and *Commiphora*. Typical grasses include species of *Aristida*, *Eragrostis* and *Urochloa*, *Digitaria eriantha*, *Brachiaria deflexa*, *Echinochloa colona*, *Cenchrus ciliaris*, *Enneapogon cenchroides*, *Pogonathria squarrosa*, and *Stipagrostis uniplumis*.

The southwestern 'Angolan' mopane covers vast regions of Namibia and Angola. Here, annual rainfall ranges from 400 to 600 mm, but is often highly unpredictable. In Namibian regions, mopane is often mono-dominant, forming dense single-species stands beneath which grass is virtually absent. In the Angolan region, mopane tends to occur as low, thorny bushland. Here it is associated with *Acacia kirkii*, *Acacia nilotica*, *Acacia hebeclada*, *Acacia erubescens*, *Balanites angolensis*, *Combretum apiculatum*, *Commiphora* species, *Dichrostachys cineria*, *Grewia villosa*, *Jatropha campestris*, *Melanthera marlothiana*, *Peltophorum africanum*, *Rhigosum brevispinosum*, *Rhigosum virgatum*, *Securinega virosa*, *Spirostachys africana*, *Terminalia*, and *Ximonia* species.

Woodland Savanna

'Woodland savanna' refers to the more mesic savannas where stands of trees occur in open formations, with some shrubs in a ground layer dominated by grasses. There are two major regions of woodland savanna in Africa – the large region called the *miombo* in central/south Africa and a smaller area called the *doka* in the north.

The miombo woodland covers an estimated 3 million square kilometers in Zimbabwe, Zambia, Mozambique, Angola, Malawi, Zaire, and Tanzania. It takes its name from the miombo tree, a species of *Brachystegia*, which is the dominant genus across this vast area. Mean annual rainfall in the center of the miombo region ranges from 800 to 1200 mm, but can decrease towards the south to 600–800 mm.

Typically, mature miombo trees are 15–20 m tall but heights can decrease in drier regions. Dominant tree species include several species of *Brachystegia*, and others such as *Marquesia macroura*, *Julbernardia globiflora*, *Julbernardia paniculata*, *Isoberlinia angolensis*, *Uapaca kirkiana*, *Monotes glaber*, *Faurea saligna*, *Faurea speciosa*, *Combretum molle*, *Albizia antunesiana*, *Strychnos spinosa*, *Strychnos cocculoides*, *Flacourtia indica*, and *Vangueria infausta*. Most of the miombo trees shed their leaves in the pronounced dry season and are bare for 2–3 months. With high productivity from the mesic rainfall regime and a long dry season that leaves the vegetation dry, fire becomes an important ecological factor in the miombo woodland.

The northern doka savanna takes its name from the dominant tree in this region, *Isoberlinia doka*. This savanna is characterized by patches of dense trees, dominated by doka along with *Azelia africana*, *Burkea africana*, *A. leiocarpus*, *Terminalia* species, and *Borassus aethiopicum*.

Forest-Savanna Mosaic

The forest-savanna mosaics, as their name suggests, occur at the mesic limits of the savanna biome where savannas transition into closed-canopy forests. The savannas at these regions are densely wooded and structurally begin to approach the appearance of slightly open forests, but grasses are still dominant in the understorey (Bond and Parr, 2010; Ratnam *et al.*, 2011).

In Africa, these mosaic regions encircle the Congo basin, and are a dynamic and shifting matrix of savanna, forest, and grassland. To the north-west is the Guinean savanna forest mosaic which extends from Guinea and Ivory Coast through to Nigeria. To the north lies the Congolian forest-savanna mosaic, which extends through the Central African Republic, the Democratic Republic of Congo and into southern Sudan, while the Zambezan forest-savanna mosaic lies to the Southwest. With mean annual rainfall in these regions ranging from 1200 to 1600 mm, the vegetation has both forest and savanna elements. Trees common to wooded grasslands are widespread in the region and include such species as *Annona senegalensis*, *A. africana*, *Burkea africana*, *Butyrospermum paradoxum*, *Stereospermum kunthianum*, *Strychnos*, *Terminalia*, and *Vitex* species. Likewise, species common to dry forest such as *A. africana*, *Aningeria altissima*, *Chrysophyllum perpulchrum*, *Cola gigantea*, *Combretum collinum*, *Morus misozhygia*, and *Khaya grandifolia* also occur. Common grasses, many growing taller than two meters, include species of the genus *Andropogon*, *Hyparrhenia*, and *Loudetia*.

Asian Savannas

In contrast to the savannas of Africa, Asian savannas have been relatively less well studied, and consequently detailed knowledge about the distribution and dynamics of the different

savanna types that occur in the region is lacking. Several factors have contributed to this lacuna.

Unlike Africa, where almost 50% of the landmass is arid to semiarid and dominated by savanna landscapes, much of continental south and Southeast Asia receives over 800 mm of rainfall annually, making forests and savanna woodlands much more dominant in this landmass. Further, historically, much of the early interest in the region's vegetation came from the perspective of timber and forestry operations of the early colonial period. Together, biogeography and history have resulted in a legacy of a markedly forest-centric approach to the understanding and study of vegetation in this region.

Most early regional vegetation classification schemes (e.g., Puri, 1960; Champion and Seth, 1968), which are still the major references used today, refer only to the 'forest types' of south and Southeast Asia with the word savanna rarely finding mention. Many vegetation formations in the Indian subcontinent that are functionally and structurally savannas, with woody tree or shrub components in a C_4 grass dominated understory, are nevertheless referred to as forests. These include the relatively open 'thorn and scrub forests' in the arid and semiarid regions of western India, and the more wooded 'mixed and dry deciduous forests' in the mesic regions of peninsular India (*sensu* Champion and Seth, 1968). Likewise, in Southeast Asian classification systems, the characteristic vegetation type of the lowland regions from northern Burma through Thailand, Laos, Cambodia, and Vietnam, an open dry deciduous dipterocarp forest with the ground covered by grasses, is variously referred to as 'forêts claire' or 'open forest' or 'savanna forest' (Boulbet, 1982; Stott, 1990). As Stott (1991) noted of these dry dipterocarp forests which bear striking similarities to the miombo woodlands of Africa: "To a large extent, these associations have been singularly neglected by scholars of savanna vegetation, and they remain very much the 'Cinderellas' of the subject, even in modern texts."

It is likely that the above nomenclature has contributed to the widespread perception that all of the open, savanna-like formations in the region today are derived, that is, they were originally forests that have been converted to savannas as a result of human activities and disturbances such as fire and grazing (Mishra, 1983; Gadgil and Meher-Homji, 1985; Yadava, 1990), but this is likely to be a misconception (Stott, 1991; Mistry, 2000; Shorrocks, 2007; Ratnam *et al.*, 2011). While it is undoubtedly true that long-term pervasive human presence has resulted in large tracts of 'derived' savannas in the region, it is also likely that several areas supported 'natural' savanna vegetation in the past, and continue to do so today (Stott, 1991; Pemadasa, 1991; Shorrocks, 2007; Ratnam *et al.*, 2011). In particular, several authors consider the dry dipterocarp forests of Southeast Asia to be natural 'climax' formations with edaphic origins on coarse sandy soils (Boulbet, 1982; Blasco, 1983; Stott, 1988, 1990). This idea is further supported by early observations in northern Thailand by Barrington (1931) who noted that "30 or 40 years of fire protection had no appreciable effect on the vegetation." Thus, even while these formations are referred to as 'forests', it is clear that their savanna-like characteristics have been long recognized.

As a consequence of the historical forest bias of vegetation scholars in this region, there is no detailed classification or

maps of the different types of Asian mixed tree–grass systems; **Figure 7** is extracted from a recent mapping of the vegetation of the region using satellite imagery (Blasco *et al.*, 1996), and while its scale of resolution does not detail different types of savanna, it provides the best available estimates of current day extents of mixed tree–grass systems in this region. Below, the authors draw on existing vegetation texts for the region (Champion and Seth, 1968; Blasco, 1983; Stott, 1984; Mistry and Stott, 1993) to reconsider the nature and extent of mixed tree–grass systems in south and Southeast Asia. In the interest of continuity, the authors retain the commonly used forest nomenclature (Champion and Seth, 1968) but focus on the tree–grass aspects and draw attention to their analogies with African savanna systems.

Dry Thorn Forests

These are open tree–grass systems of short stature with trees being 6–9 m in height. There is an assorted lower story of small trees and shrubs. There is usually thin grass growth, which appears abundant in the wet season, but much of the ground is bare in the dry season. The southern forms of this

vegetation type extend across the dry tracts of peninsular India and along the lee of the Western Ghats, where mean annual rainfall typically ranges from 500 to 800 mm. The genus *Acacia* with its many species is characteristic above all others, often associated with species of *Ziziphus*, *Capparis*, and fleshy *Euphorbia* species. Perennial grasses like *Themeda quadrivalvis*, *T. triandra*, *Thelepogon elegans*, and *Sehima nervosum* are common in the understory. The northern forms spread over the semiarid regions of central India, east of the arid Thar Desert. These are shorter than the southern thorn forests, with members of *Acacia*, *Mimosa*, and *Prosopis* being dominant. The grasses tend to be annuals rather than perennials with *Lasiurus hirsutus*, *Panicum turgidum*, *Sporobolus marginatus*, and *Cenchrus* species being common. These systems find their closest structural and compositional analogs in the ‘grass and shrub’ savannas of arid Africa.

Dry Deciduous Forests

These woodlands, many of which have grassy understories, occur throughout the Indian peninsula with typical mean annual rainfall ranging between 1000 and 1400 mm, with

Figure 7 Present day extent of mixed tree–grass vegetation in continental south and Southeast Asia at a scale of 1 : 5 million. The areas in gray represent non-savanna habitats including agricultural lands (Redrawn from Blasco F, Bellan MF, and Aizpuru M (1996) A vegetation map of tropical continental Asia at 1 : 5 million. *Journal of Vegetation Science* 7: 623–634, with permission from John Wiley & Sons; Map credit: Varun Varma).

long dry seasons ranging from 5 to 7 months. While they occur on all well drained soils, they are particularly characteristic on rocky or shallow soils. The dominant tree species are *Tectona grandis*, *Anogeissus latifolia*, and species of *Terminalia*, *Boswellia*, *Diospyros*, and *Sterculia*. Grasses tend to be of medium height with *Heteropogon*, *Themeda*, and *Saccharum* dominating. The bamboo *Dendrocalamus strictus* is also widely present. Both fire and grazing are important in these landscapes, which have historically overlapped across their range with some of the densest human populations of the peninsula. Structurally, they are most similar to the 'tree and shrub' savannas of Africa. However, the factors that differentiate the 'savanna' formation from the 'forest' formation (without grassy understories) of this habitat type are unclear.

Moist Sal Savanna

These are open deciduous formations with heavy grass that occur patchily across the central plains of the Indian peninsula. Mean annual rainfall in these regions may range from 1400 to 1900 mm. The dominant tree species is the Sal or *Shorea robusta*, in association with *Careya arborea*, *Emblia officinalis* and *Wrightea tomentosa*. Predominant grasses in the understorey include *Imperata cylindrica*, *T. triandra*, *Cymbopogon*, and *Apluda* species. Given that these formations occur within a moist forest zone, Champion and Seth (1968) consider that both frequent fires and winter frosts are significant factors driving these formations.

Dipterocarp Savanna Forests

These dry open 'forests' stretch through seasonal mainland Southeast Asia from Vietnam in the east through Cambodia, Laos, Thailand, and Burma, up to the Manipur state in Northeast India. These regions experience mean annual rainfall in the range of 800–2000 mm, with dry seasons ranging from 5 to 7 months. Dominant tree species are *Dipterocarpus intricatus*, *Dipterocarpus tuberculatus*, *Dipterocarpus obtusifolius*, *S. robusta*, *Shorea roxburghii*, and *Shorea siamensis*. Other important tree species include, amongst others, *Dillenia* species, *Pinus merkusii*, *Pterocarpus macrocarpus*, *Terminalia* species, and *Xylia kerrii*. The dominant grasses include genera such as *Arundinella*, *Capellipedium*, *Heteropogon*, *Polytoca*, *Imperata* and *Themeda*, and pygmy bamboos of the genus *Arundinera*. Also characteristic of these formations are dwarf palms of the genus *Phoenix* and cycad members of the genus *Cycas* (Stott, 1990; Mistry and Stott, 1993). Structurally, these formations find their closest analogs in the miombo woodlands of Africa and the eucalypt woodland savannas of Northern Australia.

Biodiversity in Savannas

While savannas are not generally considered high biodiversity ecosystems like rainforests and coral reefs, these seemingly simple systems are distinctive formations and harbor many unique species and assemblages.

For African savannas, where data are extensive (Figure 8), it is apparent that these are floristically diverse systems (Menaut, 1983). The average plant richness of African savannas (calculated for landscape units of 10,000 km²) is about 1750 species, with a lot of variation across savanna types, and a pattern of

increasing plant richness from arid to mesic systems (Menaut, 1983). Of particular note, the miombo savannas of East Africa harbor >3000 species, rivaling the diversity of tropical rainforests. African savannas also support distinctive mammalian herbivore and carnivore assemblages, many of which may be more species-rich than mammal communities of rainforests (Scholes and Walker, 1993; Shorrocks, 2007). The rodent fauna of African savannas are also particularly diverse (Scholes and Walker, 1993), as are the birds (Fry, 1983; Shorrocks, 2007). Over 700 bird species from 57 families, second only to tropical rainforests, have been estimated to occur in just the lowland savannas of tropical Africa, of which eight families are confined to savanna habitats (Fry, 1983).

While biome-scale diversity estimates are not yet readily available for Asian mixed tree–grass systems, an examination of smaller scale studies reveals some trends in floristic diversity. In a pattern similar to that for total floristic diversity in African savannas, woody plant diversity in the Indian subcontinent appears to increase from arid to mesic systems. Species richness of trees and shrubs ranges from 20 to 35 in dry thorn forests, increasing to about 60–80 species in dry deciduous forests (Sukumar *et al.*, 1992; Pandey and Barik, 2006; Joseph *et al.*, 2008). In comparison to woody species, species richness in the herb–grass layers in these systems appears to be much higher. In a study of 40 savanna-grassland communities in southern India, Sankaran (2009) reports 278 species of herbs and grasses in the understory, with most species highly restricted in their distribution. Likewise, Singh *et al.* (2010) report 1011 species for the tropical dry scrub forests–grassland continuum in central India, with the grasses of the *Poaceae* family (112 species) being the most diverse group. For the dipterocarp savanna forests of Thailand, Stott (1990) reports a high diversity of understory species, including many geophytes. In terms of mammalian fauna, while the ungulate and carnivore communities of Asian savanna habitats are not as diverse as those of Africa, many of these (e.g., Greater one-horned rhinoceros, tiger) are unique to the Asian region so that the shrinking extents of these habitats is a serious threat to their conservation. Asian savannas also host a characteristic avifauna, albeit poorer in species richness when compared to Africa (Fry, 1983).

Savannas and the Global Carbon Cycle

Because of their large spatial extent – they cover an area greater than that occupied by boreal or temperate forests (Mouillot and Field, 2005) – savannas play a significant role in influencing local, regional, and global climate and biogeochemical cycles. Tropical savannas and grasslands store ~326 Gt of C, accounting for ~15% of global terrestrial carbon stocks (Grace *et al.*, 2006). Savannas are also remarkably productive ecosystems, with net primary production values ranging from 1 to 12 t C ha⁻¹ depending on rainfall and woody cover (Grace *et al.*, 2006). At a global level, net primary production in savannas averages ~7.2 t C ha⁻¹ year⁻¹, paralleling that of temperate forests (7.7 t C ha⁻¹ year⁻¹) and third only to tropical rainforests (12.5 t C ha⁻¹ year⁻¹). They sequester ~0.39 Gt C year⁻¹, contributing ~15% to the annual global carbon sink.

Figure 8 Floristic richness across the African continent, collated as number of species per 10,000 km². The solid line is the equator and the dotted lines represent the tropic of Cancer and tropic of Capricorn (Reproduced from Menaut J-C (1983) *The vegetation of African savannas*. In: Bourlière F (ed.) *Tropical Savannas. Ecosystems of the World* 13, pp. 109–149. Amsterdam: Elsevier Scientific Publishing Company).

Savannas are also the most fire prone biome in the world, accounting for nearly 85% of the global land area burnt annually (Mouillot and Field, 2005). It is estimated that nearly 311 and 35 million hectares of savanna vegetation burn annually in Africa and South Asia (~55% and 6% of global burnt area, respectively), with an additional 38 million hectares of Southeast Asian savannas burnt annually (Mouillot and Field, 2005). Collectively, savanna fires account for ~1.67 Gt C year⁻¹, or half of the global carbon emissions from biomass burning (Mouillot *et al.*, 2006). Savanna fires are also important sources of NO_x (NO + NO₂) to the atmosphere, accounting for over half of that released by wildfires globally (Beerling and Osborne, 2006).

Clearly, savannas constitute an important component of the global carbon cycle. At the same time, savanna ecosystems worldwide are under intense anthropogenic pressure. Rate of loss of savanna habitats, though not well established, has been estimated to be as much as twice that of rainforests, potentially contributing a flux of carbon to the atmosphere matching that resulting from the deforestation of rainforests (Grace *et al.*, 2006). Protection of savannas from burning and grazing has been proposed as a mechanism to enhance terrestrial carbon sequestration in these biomes and worldwide (Grace *et al.*, 2006). While such measures are undoubtedly required in some regions, it is also important to recognize that these cannot be adopted as blanket measures in savannas

worldwide. Fire and grazing are both integral components of savanna ecosystems, defining not only the structure of these ecosystems but also serving to maintain the unique diversity that characterizes them (Ratnam *et al.* 2011).

The Future of the Savanna Biome: Savannas and Climate Change

Savanna structure and dynamics are the consequence of a suite of interacting factors, and changing environmental drivers are likely to have significant impacts on savanna vegetation both directly, by influencing resource availability, and indirectly through feedback effects arising from changes in top-down controls. In fact, savanna ecosystems are believed to be amongst the most sensitive biomes to future climate change (Sala *et al.*, 2000; Bond *et al.*, 2003).

The strong dependence of savanna vegetation structure on water availability suggests that future changes in rainfall, both in the total amount and seasonality, are likely to have significant impacts on woody vegetation dynamics in savannas. Climate models predict both increases and decreases in future total rainfall in many savanna regions of the globe (IPCC, 2007). In addition, many regions are also likely to witness changes in rainfall distribution across the season, with the rain falling in fewer but more intense events with longer

intervening dry periods (IPCC, 2007). Different savanna regions are therefore likely to show divergent responses depending on the exact nature of the change in local precipitation regimes. Savannas are likely to shift to more wooded states in areas where precipitation increases, and toward more open states where precipitation declines, or where the rain arrives in fewer but more intense events (Sankaran *et al.*, 2005, 2008; Good and Caylor, 2011).

Increased atmospheric CO₂, however, is likely to favor woody proliferation (Polley *et al.*, 1997; Bond and Midgley, 2000). CO₂ fertilization stimulates C₃ photosynthesis more than C₄ photosynthesis (Sage and Kubien, 2003), and is thus likely to favor C₃ trees and shrubs and give them a competitive advantage over C₄ grasses. Besides such direct effects on growth, decreased transpiration rates under elevated CO₂ can increase subsoil moisture, additionally favoring the woody component (Polley *et al.*, 1997). Further, increased growth of tree and shrub seedlings and saplings under elevated CO₂ can also hasten their escape from the grass flame zone, and increase the resprouting ability of savanna species by enhancing carbohydrate reserves (Hoffmann *et al.*, 2000), thus reducing the strength of fire-imposed bottlenecks (Bond and Midgley, 2000). In fact, large scale increases in woody cover related to regional rather than local drivers, potentially increased CO₂, have already been widely reported (Wigley *et al.*, 2010 and references therein).

In addition to changes in atmospheric CO₂ concentrations, anthropogenic activity has also resulted in an estimated 13-fold increase in global N deposition (Galloway *et al.*, 2008) and a doubling of P deposition (Filippelli, 2008). Such widespread fertilization is likely to have significant impacts on savanna vegetation structure. While increased N-deposition can potentially cause savannas to shift to more open, grassy states (Sankaran *et al.*, 2008; van der Waal *et al.*, 2009, 2011), the impact of enhanced P-deposition on savannas remains unclear.

A substantial body of literature has developed over the years on the individual effects of different climate change drivers. These different drivers are likely to elicit divergent responses in savanna vegetation. Increased rainfall and elevated CO₂ can cause shifts toward more wooded states, while lowered rainfall amounts, more intense rainfall events, longer intraseasonal droughts and N-deposition should cause shifts toward more open states. However, it is important to recognize that different drivers do not act individually, but in concert, and are changing in ways that are spatially variable across the globe (IPCC, 2007). Predicting savanna responses to future global change will therefore require a more comprehensive understanding of the interactive effects of different global change drivers. Besides the direct effects on primary producers arising from altered resource availability, different global change drivers can also have effects that cascade through to higher trophic levels and feedback to influence vegetation dynamics. For example, changes in forage quality resulting from N-deposition or elevated CO₂, or changes in surface water availability as a result of altered rainfall regimes, can influence both the amounts and spatial pattern of herbivory and fires, with implications for savanna vegetation structure and dynamics at large scales. Even while our understanding of savanna ecosystems has substantially

increased in the last two decades, more research that will enable us to better predict how the diverse savannas of the world will respond to global change is urgently needed.

Glossary

ENSO El Nino/La Nina-Southern Oscillation is a climate pattern that happens across the tropical Pacific Ocean in approximately 5-year intervals. It is characterized by variations in the ocean surface temperature and air surface pressure in the eastern and western tropical Pacific Oceans, respectively.

Indo-China Mainland Southeast Asia.

Malesia The Malay Peninsula, Malay archipelago, and New Guinea. Biogeographically, this combines Sundaland, Wallacea (including the Philippines), and New Guinea.

Recalcitrant Seeds that have high moisture content and lose viability if moisture drops below a critical amount limiting their storage for long periods.

Sahul New Guinea, Australia, and their islands.

Sundaland The Malay Peninsula along with Sumatra, Java, Borneo, and associated islands.

Wallacea Lands east and north of Borneo, west of New Guinea and East of Wallace's Line, including the Philippines, Sulawesi, Lombok, Sumbawa, Sumba, Timor, the Moluccas (e.g., Halmahera and Seram), Flores, and the other islands of Nusa Tenggara.

Introduction

Southeast Asia has been variously defined. Herein, "Malay Archipelago" states of Brunei, East Malaysia (Sabah and Sarawak), East Timor, Indonesia, the Philippines, and Singapore and the mainland states of Cambodia, Laos, Burma (Myanmar), Thailand, Vietnam, and Peninsular Malaysia are included. Australia, Bangladesh, China, India, and their island territories are excluded. Papua New Guinea and the Solomon Islands are also excluded. Indonesian Papua and neighboring islands of eastern Indonesia are included in national statistics but are judged biologically distinct from Southeast Asia proper.

The region's biota has complex origins (e.g., Morley, 2000; Briggs, 2003). Climate, sea level fluctuations, and tectonic motion have repeatedly joined and severed biotas (Morley, 2000; Wurster et al., 2010), whereas geology, terrain and climate provide diverse local environments (Zeuner, 1941).

The genus *Homo* has lived in Southeast Asia for over a million years (Corvinus, 2004). The species distributions of flora and fauna, including many fruit, bamboo, and palms, reflect millennia of human interaction. In this article, the state and trends of terrestrial, freshwater, and mangrove ecosystems in Southeast Asia are considered.

Habitat Loss, Degradation, and Recovery

Lowland and Montane Forests

The lowland rainforests of Southeast Asia are among the most diverse biomes, (Brooks et al., 2006; Normile, 2010) and globally significant terrestrial carbon sinks (Saatchi et al., 2011). The forests are vulnerable to clearance for agriculture as well as fire, mining, and unsustainable logging. The degrada-

tion of these forests also has major implications for the substantial numbers of forest-dependent rural poor (Poffenberger, 2009). Southeast Asia's forests face serious threats. The region has the highest rates of deforestation of any tropical region (Laurance, 1999, 2007), with rates between two and three times higher than those of other tropical regions (Achard et al., 2002; Sodhi and Brook, 2006). Based on current deforestation rates of 0.71% per year (Achard et al., 2002), 74% of Southeast Asia's forests could be cleared by 2100, which is predicted to cause the extinction of between 13% and 42% of all species in the region by the end of this century (Brook et al., 2003).

Based on the latest Global Forest Resources Assessment (FAO, 2010), Southeast Asia has lost 33.2 million ha of forests in the past two decades at an annual deforestation rate of 0.72% and now sustains 214.1 million ha of forests. Forests in Indonesia span 94.4 million ha, the third largest forested area of any tropical country (FAO, 2010). The great extent of Indonesia's forests, representing 44.1% of all forests in Southeast Asia, highlights the importance of this country for regional conservation efforts. However, forest cover in Indonesia declined by 24.1 million ha between 1990 and 2010 at an annual deforestation rate of 1.14% (FAO, 2010). Although the absolute area of forest loss was greatest in Indonesia, Myanmar, Cambodia, and East Timor also had annual deforestation rates exceeding 1%. In contrast, Vietnam's forest cover actually expanded during this time period, from 9.4 million ha in 1990 to 13.8 million ha in 2010, an increase of 4.4 million ha, of which most (2.5 million ha) came from planted forests. Overall, the extent of planted forests in Southeast Asia increased from 11.7 million ha in 2000 to 14.5 million ha in 2010, at an annual growth rate of 2.14% (FAO, 2010).

In insular Southeast Asia, rates of deforestation have declined in the past two decades. In the late 1990s, fires during a severe El Niño-Southern Oscillation (ENSO) event destroyed very large areas of forest in Indonesia, which could explain the higher deforestation rates in the 1990s (Miettinen *et al.*, 2011a). Within this area, the eastern lowlands of Sumatra and the peatlands of Sarawak, Borneo had exceptionally high levels of forest loss with annual rates exceeding 5%. Overall, however, Indonesia's deforestation rates appear to be slowing down; the rate between 1990 and 2000 was 1.75% per year, 0.31% per year between 2000 and 2005, and 0.71% per year between 2005 and 2010 (FAO, 2010). In mainland Southeast Asia, Thailand's deforestation rates, although already relatively low, also appear to be slowing; deforestation rates of 0.28% per year from 1990 to 2000 and 0.11% per year from 2000 to 2005 changed to a net forest increase of 0.08% per year from 2005 to 2010 (however, this may simply reflect the fact that most of Thailand's forests have already been cleared). Although changes in forest cover have stabilized in some Southeast Asian nations, much of these changes represent the replacement of primary forests with plantation or secondary forests, which offer less conservation value (Gibson *et al.*, 2011).

The area of primary forest in Southeast Asia decreased from 66.3 million ha in 2000 to 64.0 million ha in 2010, a loss of 2.3 million ha (FAO, 2010). Indonesia suffered the greatest loss of primary forest among any nation, losing 2.0 million ha between 2000 and 2010 at an annual rate of 0.42%. Cambodia lost the next largest amount of primary forest and had the highest annual rate of primary forest loss of 3.48%, and Brunei (0.91%) and Vietnam (0.85%) also experienced high rates of primary forest loss. However, several nations in Southeast Asia reported no change in the extent of primary forests between 1990 and 2010, including Laos, Malaysia, Myanmar, the Philippines, Singapore, Thailand, and East Timor.

Secondary forests may represent a key habitat for biodiversity conservation in Southeast Asia because of their great extent and their potential to regenerate into old-growth forests (Koh, 2007; Chazdon *et al.*, 2009). Although secondary forests were not included in the most recent Forest Resources Assessment, based on the previous assessment, secondary forests comprised 67.5% of the total native forest area (FAO, 2005; Koh, 2007). These potentially critical forests continue to be lost at rapid rates in almost all Southeast Asian nations, with the exception of Vietnam, the only country in Southeast Asia where the extent of secondary forests actually increased between 1990 and 2005.

Hosting half the world's cloud forests, with a total area of 32 million ha, Southeast Asia's montane forests are also under threat (Sodhi and Brook, 2006). Although these montane forests receive considerably less attention than their lowland counterparts, representing less than 10% of studies on biodiversity conducted across Southeast Asia's major terrestrial and freshwater ecosystems, they are important ecosystems and support exceptional levels of biodiversity (Peh *et al.*, 2011). Rates for lowland evergreen forests (1.2% per year) were higher than for montane forests (0.1% per year) in insular Southeast Asia (Miettinen *et al.*, 2011a). These forests are also highly threatened and are disappearing at much faster rates compared with lowland tropical forests in the region

(Waggener and Lane, 1997). Indonesia, which has the greatest cover of montane forests at 19.5 million ha, is losing these forests at a rate of 3.05% per year from 2000 to 2005, a full order of magnitude higher than its rate of total forest loss for the same time period (FAO, 2005). Other countries in Southeast Asia that have more than a million hectare of montane forests include Malaysia, Myanmar, Thailand, and Vietnam. Although total forest cover is increasing in Vietnam, montane forests are disappearing from this country at a rate of 1.14% per year (FAO, 2005).

Singapore is a small island country located in the heart of Southeast Asia. In the past two centuries, more than 99% of Singapore's original forests were destroyed, leading to major losses of biodiversity (Corlett, 1992; Brook *et al.*, 2003). Singapore represents a worst-case environmental scenario that other nations in the region might be trending toward. For example, Java, the smallest of Indonesia's five large islands (the others being Borneo, Sumatra, Sulawesi, and Papua) and one of the most densely populated islands in the world with a population of more than 130 million people, now retains just 7% forest cover (Miettinen *et al.*, 2011a). Similarly, almost 90% of Thailand's original forests have been cleared (FAO, 2010), and continued agricultural and urban developments will only further reduce the extent of forests elsewhere in Southeast Asia. These examples suggest that similar losses in biodiversity will result throughout Southeast Asia unless ongoing clearance of forest is greatly restricted.

Rivers, Peat Swamp Forests, and Mangroves

To meet the increasing anthropogenic demand for food, water, and energy, freshwater ecosystems across the world are being extensively altered through the building of dams (Dudgeon, 2000b; Nilsson *et al.*, 2005), pollution (Driscoll *et al.*, 2007), introduction of exotic species (Leprieur *et al.*, 2008; Sanderson *et al.*, 2009), conversion of natural habitats (Allan and Flecker, 1993; Sanderson *et al.*, 2009), and the direct overharvesting of biological resources (Humphries and Winemiller, 2009). This section serves to highlight the causes, state, and consequences of habitat loss and degradation, as well as discuss the prospects of recovery, in two main inland aquatic and semiaquatic systems in Southeast Asia: rivers and streams, and peat swamp forests (PSFs), as well as a coastal aquatic system: mangroves (Figure 1).

Rivers and Streams

The biodiversity in rivers and streams in Southeast Asia are threatened by a myriad of anthropogenic activities. Deforestation/land-use change within a drainage basin (Figure 2) is one of the major threats to biodiversity in tropical freshwaters (Dudgeon, 2000a; Winemiller *et al.*, 2008) and especially so for Southeast Asia where deforestation rates are highest across the tropics in the period 1990–1997 (Achard *et al.*, 2002). Deforestation in the drainage basin and riparian zone leads to increased runoff, sedimentation, and incidence of flash floods (Dudgeon, 1999), thereby changing the natural seasonal flow regime of river systems. Sedimentation negatively impacts fish communities by reducing habitat complexity, altering available food types (Berkman and Rabeni, 1987), reducing

Figure 1 Main freshwater habitats across an altitudinal gradient. (a) A hill stream of the upper Katingan basin in Central Kalimantan, Indonesia. (b) A lowland swamp forest stream in Singapore. (c) A large river channel (Kahayan River) in Central Kalimantan, Indonesia (Photos: Heok Hui Tan (a) and (c)).

Figure 2 (a) Deforested hill stream and (b) lowland stream in Kalimantan, Indonesia.

foraging efficiency (Bergstedt and Bergersen, 1997), and reducing spawning success (Burkhead and Jelks, 2001; Sutherland, 2007). Sedimentation may also lead to increased water turbidity and a reduction in primary production owing to decreased light penetration (Kottelat and Whitten, 1996), thus affecting river food webs. The removal of riparian vegetation also reduces the food availability for fishes that depend on

allochthonous food sources, for example, terrestrial insects and terrestrial plant material (Inger and Chin, 1962; Knöppel, 1970; Dudgeon, 1983). In Sarawak, Malaysian Borneo Iwata *et al.* (2003) demonstrated that riparian deforestation (through slash-and-burn agriculture) increased sedimentation and lowered the abundance and/or diversity of benthic taxa (periphyton, aquatic insects, shrimps, crabs, and benthic

fishes) in hill streams. In Singapore, deforestation and canalization has led to the extinction of 11 (out of 46) native freshwater fishes (Giam *et al.*, 2011b).

Impoundments and dams are a major threat to the biodiversity of rivers in Southeast Asia. The impact of dams is greatest in the large rivers of mainland Southeast Asia, for example, Chao Phraya, Mekong, and Salween. In particular, proposed impoundments along the Mekong River have attracted considerable attention from conservationists and fishery scientists (Dudgeon, 2000b; Dugan *et al.*, 2010; Baran *et al.*, 2011; Ferguson *et al.*, 2011). As of 2009, 124 dams are already operating, under construction, or planned along the tributaries of the Lower Mekong, with a projected capacity of 29,760 M when completed (Mekong River Commission, 2010). Along the main stem (primary downstream segment) of the Upper Mekong in China, four dams (Manwan, Dachaoshan, Jinghong, and Xiaowan) have already been completed, with a further three in the construction or planning stage (Mekong River Commission, 2010). No dam currently exists along the main stem of the Lower Mekong, but 11 projects are being proposed, most of which are in Lao PDR (Mekong River Commission, 2010; Baran *et al.*, 2011; Ferguson *et al.*, 2011).

Dams impact both upstream and downstream freshwater biota in a variety of ways. First, the flooding that occurs upstream of the dam creates a new still water (lentic) habitat, which is oxygen poor (anoxic) and affected by sedimentation (Nilsson *et al.*, 2005). Fish and other freshwater organisms adapted to flowing waters may become locally extinct. At the same time, by trapping coarser grained and greater quantities of sediments upstream, dams alter the sediment transport regime in downstream regions, which in turn leads to changes in habitat quality for fish and other organisms (Poff *et al.*, 1997; Roberts, 2001; Poff and Hart, 2002). Second, dams alter the natural flood pulse of the river system, which contributes to the drying out of wetlands (Lemly *et al.*, 2000), and a reduction in the size and productivity of the floodplain system, and reduces the amount of food available for predatory fish (Wootton *et al.*, 1996). Third, dams fragment what were previously continuous, free-flowing habitats, preventing obligate migratory fish from completing their migrations to reproduce or feed (Roberts, 2001; Dugan, 2008). At the same time, by isolating small fish populations and preventing gene flow between adjacent populations, dams reduce the overall genetic diversity in the isolated populations (Williams, 2006). The impacts of dams on Southeast Asian biodiversity have been clearly documented. For example, the impoundment of Pak Mun Dam on the Mun River, a tributary of the Mekong in Thailand, resulted in declines in fish species richness both downstream and upstream of the dam (Roberts, 2001) and declines in species richness and ichthyomass in the reservoir area (Jutagate *et al.*, 2001).

Pollution affects most freshwater systems in the world (Dudgeon *et al.*, 2006) and Southeast Asia is no different (Dudgeon, 1992, 2000a). Rapid population growth, and intensive agriculture and industrial development have contributed to the deterioration of water resources. Untreated municipal and industrial wastes released into rivers are major problems in most Southeast Asian countries (Ministry of Natural Resources and Environment, 2006; Department of

Figure 3 Floating toilets constructed in a lowland stream in Kalimantan Tengah, Indonesia. Municipal waste is disposed streamside, whereas human waste is released directly into the stream.

Environment Malaysia, 2007; Mekong River Commission, 2007; Thailand State of Pollution Report Working Group, 2011) (Figure 3). Urban sewage increases biochemical oxygen demand and subsequently decreases the amount of dissolved oxygen in water, resulting in a reduction of aquatic biodiversity (Ramírez *et al.*, 2008). Runoff in agricultural areas, which is rich in fertilizers, may also lead to eutrophication thus threatening river and stream biodiversity. Effluents discharged by industries along the Chao Phraya River in Thailand have resulted in heavy metal pollution and their accumulation in several fish species at the river mouth (Polprasert, 1982). In the Kelian River in Kalimantan, Indonesian sediment pollution due to open-cut gold mining resulted in a decline in macroinvertebrate richness and abundance as well as food web complexity (Yule *et al.*, 2010).

The threats outlined above often function synergistically to further threaten fish biodiversity and other organisms. For example, plantation conversion in Southeast Asia is likely to impact fish not only through increased sedimentation and water temperature, but also pesticide and fertilizer pollution. The building of hydroelectric dams may also speed up industrial development that may compound pollution problems if unmatched by the development of sewage treatment facilities (Dudgeon, 2000b). Sometimes the conservation impacts may go beyond aquatic environments. For example, the inundation of human settlements upstream of dams may lead to the migration of people into nearby forests resulting in forest degradation and further biodiversity impacts.

PSFs and Blackwater Streams

PSFs – a lowland forest ecosystem formed on peat soils that is derived from woody plant debris in areas with high rainfall, high temperature, and poor drainage (Posa *et al.*, 2011) – are mainly found on the islands of Sumatra, Borneo, and Peninsular Malaysia. Most of these PSFs are ombrogenous: they obtain their nutrients directly from rain and plant remains only (Whitmore, 1984). It can be classified as a semiaquatic system as the rain-fed water table fluctuates with changes in rainfall intensity but always remains close to or above the peat surface throughout the year (Page *et al.*, 1999). The tea-colored

water draining from PSFs is very acidic (pH 3–4.5), owing to the high concentration of humic acid and tannins (Whitten *et al.*, 2000) and is commonly termed “blackwater.”

Despite being poorly drained and relatively infertile, Sundaland’s PSFs are being converted to industrial-scale forestry and monoculture plantations at alarming rates (Koh *et al.*, 2011b; Miettinen *et al.*, 2011b). Among the different sub-regions, the rate of loss is highest in Sarawak (– 8.1% per annum) and Sumatra (– 5.2% per annum). Across the region, only 47 833 km² of PSFs remain, approximately 36% of their historical extent.

The high rates of deforestation in the blackwaters of PSFs are likely to threaten its unique assemblage of fish species via a number of processes. Clearance of PSFs stops the supply of senesced leaves that provides the likely basal resource for the aquatic foodweb – dissolved organic carbon (Yule, 2010). Where PSFs are converted to plantations, the physicochemical properties of the blackwaters are likely to change owing to burning, drainage, and the application of lime (to increase pH of peat) and fertilizers (Yule, 2010). In addition to biodiversity impacts, the degradation and conversion of PSFs also lead to the loss of substantial amounts of biomass and soil carbon (Koh *et al.*, 2011b).

Mangroves

Mangroves are forests that occur in marine or brackish environments along sheltered estuaries and river banks (Giesen *et al.*, 2006; FAO, 2007). They provide important ecosystem services for both humans (e.g., fuel wood and construction material) and wildlife (e.g., breeding nursery for fish and crustaceans) (Giesen *et al.*, 2006). Southeast Asia originally harbored more than 6.3 million ha of mangroves, the largest mangrove area of any region in the world (Giesen *et al.*, 2006). However, a sizeable proportion of these mangrove forests have since been converted. According to FAO (2007), 1.7 million ha of mangroves have been cleared between 1980 and 2005 in Southeast Asia. In terms of area, mangrove loss was highest in Indonesia; 1.3 million ha of mangroves were cleared at a rate of 1.5% annually. In terms of percentage loss, Timor-Leste and Vietnam were the highest in the region, experiencing an annual loss of 3.4% and 2.1%, respectively (Table 1). The loss of mangroves can be attributed to commercial logging that includes charcoal and fuelwood, aquaculture, agriculture, and conversion for human settlements (Giesen *et al.*, 2006; FAO, 2007; Spalding *et al.*, 2010). The main drivers of conversion are different for each country (Giesen *et al.*, 2006) and the reader is referred to the excellent country-level reviews by Giesen *et al.* (2006), FAO (2007), and Spalding *et al.* (2010).

Prospects of Recovery

For these habitats to recover, habitat degradation must first be abated. However, conservation strategies must incorporate human development goals for them to be practicable and effective (Dudgeon, 1992; Giam *et al.*, 2011a). High rates of deforestation in the last 20 years (Achard *et al.*, 2002; Miettinen *et al.*, 2011a, b) suggest that forest loss and conversion is unlikely to cease in the near future. To slow down forest loss and conserve intact forested watersheds, one possible strategy is to shift agricultural expansion into

Table 1 Decrease in mangrove area in Southeast Asia from 1980 to 2005

Countries	Area (ha)		Change 2005–1980		
	1980	2005	Area (ha)	%	% yr ^{–1}
Brunei	18,400	18,400	0	0.0	0.0
Cambodia	91,200	69,200	– 22,000	– 24.1	– 1.1
Indonesia	4,200,000	2,900,000	– 1,300,000	– 31.0	– 1.5
Malaysia	674,000	565,000	– 1,09,000	– 16.2	– 0.7
Myanmar	555,500	507,000	– 48,500	– 8.7	– 0.4
Philippines	295,000	240,000	– 55,000	– 18.6	– 0.8
Singapore	500	500	0	0.0	0.0
Thailand	280,000	240,000	– 40,000	– 14.3	– 0.6
Timor-Leste	4250	1800	– 2450	– 57.6	– 3.4
Vietnam	269,150	157,000	– 112,150	– 41.7	– 2.1
Total	6,388,000	4,698,900	– 1,689,100	– 26.4	– 1.2

Source: Mangrove area data collated from FAO (2007) The world’s mangroves 1980–2005: A thematic study prepared in the framework of the global forest resources assessment 2005. *FAO Forestry Paper 153*. Rome, Italy: Food and Agricultural Organization of the United Nations.

Note that Lao PDR is excluded from the table as it is a landlocked country with no mangrove forest

degraded lands. This must be coupled with the development of wastewater treatment facilities and tighter regulation of pesticide and fertilizer use (Dudgeon, 1992) in these areas. The carbon payment scheme known as Reduced Emissions from Deforestation and Forest Degradation *plus* conservation, sustainable management of forests, and enhancement of forest carbon (REDD+) (UNFCCC, 2010) might help fund the conservation of intact areas, especially carbon-rich PSFs. In watersheds where the complete protection of forests is not possible, riparian buffers should be established to mitigate the effects of sediment (Ziegler *et al.*, 2005; Lorion and Kennedy, 2009) and nutrient pollution (Peterjohn and Correll, 1984).

The development of hydroelectric dams is likely to continue given the rising energy demands of the region (Dudgeon, 1992). Future development of dams should take into account the trade-offs between economic benefits and impacts to biodiversity and human livelihoods. The opening of water channel (sluice) gates during fish migration periods may help to maintain the biological connectedness of rivers. For example, when all the sluice gates of the Pak Mun Dam were opened between July 2001 and June 2002, some recovery of fish species richness, including migratory fish, was observed (Jutagate *et al.*, 2005).

The rate of mangrove conversion in Southeast Asia has not slowed down substantially for the last 20–25 years (Giesen *et al.*, 2006; FAO, 2007; Spalding *et al.*, 2010). Despite the bleak outlook for mangroves, there are causes for optimism. As biological and economic impacts of mangrove conversion (e.g., coastal fisheries productivity declines (Barbier, 1993)) become better understood, mangroves are increasingly being protected (Spalding *et al.*, 2010) and rehabilitated or restored (Macintosh *et al.*, 2002; Giesen *et al.*, 2006). Strategies for restoration are reviewed in Giesen *et al.* (2006). In addition to the rehabilitation and restoration of degraded mangroves, governments must muster the political will to stop degradation of the remaining intact mangroves of the region.

Species Status and Trends

Plants

Southeast Asia possesses an estimated vascular flora of around 60,000 species (20,000–25,000 species in Indo-China and 42,000 species in Malesia; Frodin, 2001). A generic level count for the regional flora is provided in Table 2. Species level summaries are less certain but Indonesia alone has an estimated 38,000 species of which around 18,700 are endemic (BAPPENAS, 2003). For example, Mt Kinabalu in Sabah, Borneo has around 5000 species in 1200 km² (Beaman, 2005). Plant diversity peaks in the wet equatorial lowland forests of Borneo, Sumatra, and Peninsular Malaysia. The 52-ha plot at Lambir, Sarawak, averages 247 species of tree over 10-cm diameter per hectare and possess 1003 such tree species in total (Losos and Leigh, 2004). A nondestructive survey of all vascular plants in just 200 m² of lowland forest in Tesso Nilo, Sumatra cataloged 217 species (Gillison, 2001).

The flora remains incompletely known. As recently as the year 2000, Laos's main commercial rattan was undescribed (Prance *et al.*, 2000). In Borneo 15–35% of the flora likely remains uncollected (Beaman and Burley, 2003). Surprisingly, some estimates suggest that, although three-quarters of Southeast Asia's mosses (76%) are already known, knowledge of at least some higher plants is considerably less (only 28% complete for the Fabaceae; see Giam *et al.*, 2010b).

Of 1371 red-listed plant species in Southeast Asia, 292 are critically endangered, 196 endangered, 737 vulnerable, 31 near-threatened, and 110 data-deficient. Five plant extinctions are documented: two mangos (*Mangifera casturi* Kosterm and *Mangifera rubropetala* Kosterm), two dipterocarp trees (*Dipterocarpus cinereus* Soot and *Shorea cuspidata* Ashton), and one herb – the “woolly stalked Begonia” (*Begonia eiromischa* Ridl.). Only the mangos survive in *ex situ* collections (IUCNRedlist.org, accessed 23 August 2011). A recent detailed assessment of the 155 Dipterocarp trees of Peninsular Malaysia finds that five of them are critically endangered, 35 are endangered, 42 are vulnerable, and 46 are near-threatened (Chua *et al.*, 2010).

One endemic species, *Shorea kuantanensis* P.S. Ashton, is judged extinct, whereas nine of 11 other considered possible extinct in a previous summary (Symington, 2004) have been rediscovered (Chua *et al.*, 2010).

Although ecological relationships are poorly explored, the region's pollination systems are considered relatively robust (Corlett, 2004). Exceptions include figs (*Ficus* spp.) where loss of Agaonidae wasp pollinators and thus of viable seed production has been observed following droughts (Harrison, 2000). There are concerns with bat-pollinated species such as durian and pete/petai (*Durio* spp. and *Parkia* spp.) but data are lacking. Comparison suggests that loss of vertebrate seed dispersers is generally a greater and more immediate concern than loss of pollinators – although both remain concerns in the longer term (Corlett, 1998, 2004).

Insects

The effects of land-use change and deforestation on the megafauna of Southeast Asia have been well reported (Sodhi *et al.*, 2009). However, the responses of less “charismatic” groups, such as insects, to habitat disturbance remain relatively poorly understood (Dunn, 2005). This is alarming, considering the global dominance of insects among animal communities in terms of species richness, abundance, and biomass (Wilson, 1987), as well as the overarching importance of insects in providing ecosystem services for human societies (e.g., pollination of crops) (Nabhan and Buchmann, 1997).

Data on the conservation status of insects are scarce because the International Union for Conservation of Nature (IUCN) Red List is highly biased toward larger and better studied taxa (e.g., vertebrates; Rodrigues *et al.*, 2006). In Southeast Asia, 87 terrestrial insect species are listed as threatened on the IUCN Red List, which represents 12% of total threatened terrestrial insect species worldwide. These threatened species are classified as “critically endangered” (CR), “endangered” (EN), or “vulnerable” (VU; IUCN, 2011). Of the 87 threatened terrestrial insect species, 43 are

Table 2 Generic richness by regions in Southeast Asia

Region	Genera	Endemic genera	Genera standardized by area ^a	Genera standardized by collecting intensity ^a

Source: Reproduced from Marsh ST, Brummitt NA, de Kok RPJ, and Utteridge TMA (2009) Large-scale patterns of plant diversity and conservation priorities in South East Asia. *Blumea* 54: 103–108, with permission from Nationaal Herbarium Nederland.

Lepidoptera (butterflies or moths – CR: 1, EN: 14, and VU: 28) and 42 are Odonata (dragonflies or damselflies – CR:6, EN: 9, and VU: 27). There is also one vulnerable ant species (*Monomorium hospitum*; VU) and one extinct stick insect (*Pseudobatrachia ridleyi*). Because of the high proportion of endemic species in Southeast Asia, the loss of many of these threatened species likely will result in global extinctions.

Butterflies are among the best-studied insect groups in Southeast Asia in terms of taxonomy and biogeography (D'Abrera, 1982, 1985, 1986; Corbet and Pendlebury, 1992; Igarashi and Fukuda, 1997, 2000). They are highly sensitive to habitat disturbance and have commonly been used as an indicator taxon for ecological research (Koh and Sodhi, 2004). Most field studies reveal that deforestation has significant impacts on butterfly diversity. For example, Willott *et al.* (2000) found that primary forests in the Danum Valley in Borneo had significantly lower species richness (121 ± 3 vs. 151), Fisher's α -diversity (31 ± 3 (95% confidence interval) vs. 40 ± 4) and rarified species richness (120 ± 3 vs. 143 ± 4) than secondary logged forests.

Apart from the Lepidoptera, bees are the other insect group that has been relatively well studied in this region. Liow *et al.* (2001) found that below-canopy bee abundance was significantly higher in primary forests than in other land uses. In Sumatra and Indonesia, primary forests were also shown to contain higher bee richness, diversity, and abundance than disturbed lands, such as plantations (Sakagami *et al.*, 1990). Dung beetles is another group that have been the focus of ecological studies often because of the ecosystem services they provide, including nutrient cycling and seed dispersal (Davies *et al.*, 2001). Not surprisingly, a study on the impacts of forest conversion to *Acacia* and *Albizia* plantations in Sabah demonstrated that beetle species that are closely associated with primary forests were most negatively affected by forest conversion (Davies *et al.*, 2001). Termites and ants also provide important ecosystem services. In Sumatra, the species richness and relative abundance of termites were highest in primary forests compared with secondary forests and agricultural lands (Jones *et al.*, 2003). Furthermore, of the 34 termite species recorded in primary forests, only one could be found in cultivated areas. Similarly, Bruhl *et al.* (2003) found that less than half of the leaf litter ant species in contiguous forests were recorded in forest fragments.

Reptiles and Amphibians

Amphibians

Southeast Asia is a hotspot for amphibian species richness and endemism (Bickford *et al.*, 2010). More than 730 species of amphibians have been described for the region (IUCN, 2011) and many more are likely undescribed (Giam *et al.*, 2010a, 2011c). The conservation status of most amphibians has been assessed as a result of the 2004 Global Amphibian Assessment (Stuart *et al.*, 2004) and subsequent yearly assessments by IUCN (IUCN, 2011). Of the 738 native amphibians assessed on the 2011 IUCN Red List, 135 are threatened with extinction (i.e., Red List categories, critically endangered, endangered, or vulnerable), while a further 76 are near-threatened. Many species are poorly known (Rowley *et al.*, 2010); 268 species

were categorized as data-deficient, that is, their conservation status could not be accurately assigned due to lack of data. In particular, all but one of the 24 caecilians (amphibians that superficially resemble earthworms or snakes) native to the region were classified as data-deficient. Population trends (in terms of population and range size) of 268 species are deteriorating, whereas those of 314 species are currently unknown.

Habitat destruction associated with logging and agricultural conversion is a major threat to amphibians in Southeast Asia (Bickford *et al.*, 2010) as most of the region's amphibians are forest specialists (Rowley *et al.*, 2010). In Sulawesi, Indonesia, amphibian species richness and abundance were higher in primary and secondary forests compared with agroforests and open areas (Wanger *et al.*, 2010). Illegal logging, in addition to mercury and sediment pollution resulting from illegal gold mining, is threatening the persistence of the only known lungless frog in the world (*Barbourula kalimantanensis*; Bickford *et al.*, 2008). Overexploitation of amphibians for food, traditional medicine, and the pet trade are major threats to amphibians in Southeast Asia (Rowley *et al.*, 2010). Predicted climate warming is likely to exacerbate the impacts of habitat degradation and overexploitation (Bickford *et al.*, 2010).

Reptiles

In 2008, Southeast Asia (excluding Philippines and islands east of Western Nusa Tenggara) harbored 975 native reptile species (Das, 2010). However, the conservation status of most of these species remains unknown – less than a quarter have been assessed by the IUCN as of October 2011 (IUCN, 2011). The proportion of species that were assessed differed across major groups of reptiles. The conservation statuses of crocodiles (83% of species assessed; 5 of 6 species) and turtles (75%, 40 of 53 species) were better elucidated compared to snakes (27%, 132 of 484 species) and lizards (15%, 65 of 432 species). Of the 242 species that were assessed, 50 species were found to be threatened (i.e., categorized as critically endangered, endangered, or vulnerable). A further 80 species were classed as data-deficient. Based on available species assessments, the crocodiles and turtles appear to be most threatened. Thirty-five of 40 assessed turtle species and four of five assessed crocodile species were deemed to be threatened. The main threats to turtles appear to be from the wildlife trade, bushmeat hunting, degradation of habitat for nesting (for sea turtles), pollution, and bycatch mortality (i.e., mortality from entanglement in fishing nets; Shanker and Pilcher, 2003; Pacini and Harper, 2008; Nijman, 2010; IUCN, 2011). Crocodiles are threatened mainly by habitat degradation (Pacini and Harper, 2008); persecution and exploitation for bushmeat and wildlife trade are also important threats (IUCN, 2011).

The low proportion of threatened lizards and snakes (relative to turtles and crocodiles) may have arisen partly due to a lack of information on population and range trends of many species. Many of the data-deficient and unassessed species may actually be threatened. For example, Thirakhupt's Bent-Toed Gecko (*Cyrtodactylus thirakhupti*) is restricted to a single cave in a forested limestone hill in Surat Thani province, Southern Thailand (Pauwels *et al.*, 2004; Das, 2010) and is

likely to be classified as threatened owing to its highly restricted range. To inform conservation priorities, the conservation statuses of unassessed species must be elucidated as soon as possible. Habitat degradation is listed as the main threat to the two red-listed lizards (*Bronchocela smaragdina* and *Cyrtodactylus cavernicolus*) and many of the threatened snakes (IUCN, 2011). As the majority of range-restricted reptiles are confined to the rapidly diminishing lowland rainforests (Das, 2010; Miettinen *et al.*, 2011a), species declines are imminent.

Birds

Birds represent one of the best-studied groups in Southeast Asia. Among the main tropical regions in the world, Southeast Asia has the highest mean proportion of country-endemic (9%) and the highest mean proportion of threatened bird species (6%; Sodhi *et al.*, 2010a). The relatively high degree of endangerment may be related to the high rate of recent deforestation observed in this tropical region. Up to 67% of forest bird species have been lost as a result of more than 90% forest loss in the highly urbanized Singapore representing one of the world's highest estimates of long-term loss of forest species (Castelletta *et al.*, 2000). In addition, local extinctions have also been reported for small, yet largely forested Indonesian and Malaysian islands (Trainor, 2007; Sodhi *et al.*, 2010b). Using estimates of forest loss and the species area relationship, Brook *et al.* (2003) projected that between 16% and 32% of Southeast Asian forest bird species will become extinct by 2100.

Endemic forest species of insular Southeast Asia have been shown to be negatively affected by deforestation and various forms of agricultural land use (Indonesia, Lee *et al.*, 2007; Maas *et al.*, 2009; the Philippines, Posa and Sodhi, 2006). For example, more sensitive species such as woodpeckers may take a longer time to reach predisturbance levels (Styring and Ickes, 2001). However, some bird communities did recover after several decades (Wong, 1986; Yap *et al.*, 2007). In fact, some logged forests in Southeast Asia can support similar or even higher species richness of birds than undisturbed forests, which may be due to improved conditions for widespread forest edge species (Johns, 1996; Edwards *et al.*, 2011). Similarly, human-modified habitats such as rubber and oil palm plantations or cacao and coffee agroforests may have higher bird species richness than open and more disturbed habitats, but the species similarity with forests is often extremely low (Aratrakorn *et al.*, 2006; Danielsen and Heegaard, 1995; Peh *et al.*, 2005; Sodhi *et al.*, 2005a; Waltert *et al.*, 2004). For instance, only 27% of observed forest species were also found in coffee plantations in Sumatra (Philpott *et al.*, 2008).

High densities of tall shade trees and proximity to natural forest may improve overall conservation value of agroforests (e.g., in cacao; Abrahamczyk *et al.*, 2008; Clough *et al.*, 2009). Having tall forest trees in otherwise altered agricultural landscapes (oil palm, cacao, and rubber) and the protection of forest fragments could be an alternative to protected primary forest fragments and are particularly critical for the remaining widespread, disturbance-tolerant forest species (Abrahamczyk

et al., 2008; Castelletta *et al.*, 2005; Clough *et al.*, 2009; Peh *et al.*, 2006; Sodhi *et al.*, 2005b). However, small fragments (<100 ha) have been shown to continue to lose species even decades after isolation and are colonized by generalist nest predators such as house crows (*Corvus splendens*; Sodhi *et al.*, 2005c, 2006a). Overall, with increasing land-conversion pressure for industrial-scale agriculture productions (e.g., oil palm), the long-term persistence of native Southeast Asian forest bird species appears to be particularly in jeopardy.

Mammals

Southeast Asia hosts exceptional levels of mammal diversity, with the highest degrees of endemism of any tropical region (Sodhi *et al.*, 2010b). However, mammals in Southeast Asia also have the highest proportion of threatened species among any tropical region (Morrison *et al.*, 2007; Schipper *et al.*, 2008; Sodhi *et al.*, 2010b), and an estimated 85% of species are at risk of extinction during this century due to deforestation (Sodhi and Brook, 2006). A recent meta-analysis found that mammals were the most sensitive taxonomic group to forest disturbance in Southeast Asia (Sodhi *et al.*, 2009), suggesting that they are most adversely affected by increasing human pressures in the region.

Forest loss and disturbance affect mammals in different ways. Despite general trends of decreased diversity and abundance (Sodhi *et al.*, 2009), many species are able to persist or recover following forest degradation (for a comprehensive review, see Sodhi *et al.*, 2010a). In Borneo, selectively logged forests can support large numbers of mammal species (e.g., the tarsier *Tarsius bancanus*), but the response varies by species based on ecological requirements (Meijaard *et al.*, 2008). In northern Borneo, small mammal diversity was lower in selectively logged forest sites compared to undisturbed forests; however, logged forests retained many species found in undisturbed forests, highlighting the conservation value of these forests (Wells *et al.*, 2007). Secondary forests in northern Borneo were also found to support diverse assemblages of up to 27 different mammal species, but Acacia and oil palm plantations offered little to no support (Bernard *et al.*, 2009; McShea *et al.*, 2009). The Philippines hosts an impressive mammal assemblage, with 90% of its more than 100 nonvolant species found nowhere else (Rickart *et al.*, 2011). In northern Luzon Island, species richness of small mammal was greatest in undisturbed forest habitats, but moderately disturbed forests also supported high levels of diversity and abundance (Rickart *et al.*, 2011).

Bats comprise a third of all Southeast Asian mammals, and of Southeast Asia's 330 species, 60% are endemic to the region (Kingston, 2010). Despite this, bats remain some of the least known vertebrates of Southeast Asia and 40% of species are predicted to be extinct by 2100 due to deforestation (Kingston, 2010). Although forest loss in the region continues, large forest fragments in Peninsular Malaysia can retain high levels of bat diversity (Struebig *et al.*, 2010).

Other mammals in the region are at high risk of extinction due to illegal poaching. Southeast Asia's pangolin species are threatened by trade for use in food, medicine, and clothing, particularly in Vietnam and China (Newton *et al.*, 2008).

Vietnam's primates are also highly threatened by poaching, with 21 of 24 species listed as threatened (Nadler *et al.*, 2007). Although hunting has greatly reduced populations of large ungulates throughout Southeast Asia, some populations have recovered following regulation of illegal poaching (e.g., the muntjac *Muntiacus muntjak*; Steinmetz *et al.*, 2010).

Large mammals may face the greatest threats because they are particularly vulnerable to habitat loss and are often targeted for hunting. Three of the region's flagship species, rhinos, elephants, and tigers, persist in isolated pockets of forest throughout their historic ranges and are increasingly rare throughout Southeast Asia (Clements *et al.*, 2010a; Lynam, 2010). In Sumatra, tigers were found in both primary and selectively logged forests, but tiger densities were higher in primary forests, probably because selectively logged forests offer greater access to hunters (Linkie *et al.*, 2008). Although secondary and selectively logged forests both sustain populations of elephants and tigers in Malaysia, the conversion of forests into agriculture has destroyed large areas of critical habitat for these species (Clements *et al.*, 2010a). Agricultural expansion has also led to human-wildlife conflicts that often result in the death of these endangered animals (Nyhus and Tilson, 2004; Clements *et al.*, 2010a).

Threats to Biodiversity

Industrial Agriculture

Industrial agriculture has become an increasing threat of forests and biodiversity across the tropics (Rudel *et al.*, 2009a, b). In Southeast Asia, oil palm agriculture has been expanding at an astonishing rate of 470,000 ha per annum between 1999 and 2009 (FAO, 2011). Currently, Indonesia and Malaysia produce 170 million metric tons of oil palm fruits each year, which accounts for 80% of the global production (FAO, 2011).

Conversion of natural habitats into a monoculture such as oil palm, almost by definition, implies a drastic loss in biodiversity. In fact, oil palm plantations contain less than half as many vertebrate species as primary forests (Fitzherbert *et al.*, 2008). Forest bird species declined by 73–77% (Koh and Wilcove, 2008), and only 10% of mammal species were detected in oil palm plantations (Maddox *et al.*, 2007). Endangered species such as the Sumatran tiger (*Panthera tigris sumatrae*), tapir (*Tapirus indicus*), and clouded leopard (*Neofelis nebulosa*) have not been recorded in oil palm plantations; and most mammals prefer marginal and heavily degraded lands (e.g., shrublands) to oil palm (Maddox *et al.*, 2007). Mammals that do occur in oil palm plantations tend to be of low conservation concern and are dominated by a few generalist species such as the wild pig (*Sus scrofa*), bearded pig (*Sus barbatus*), leopard cat (*Prionailurus bengalensis*), and common palm civet (*Paradoxurus hermaphroditus*).

The impacts of industrial agriculture on invertebrates are more variable compared with vertebrates (Fitzherbert *et al.*, 2008). Conversion of forests to oil palm resulted in 79–83% declines in the species richness of forest butterflies (Koh and Wilcove, 2008). However, ants, moths, and bees demonstrated a higher tolerance for the oil palm habitat (Danielsen *et al.*, 2008). Nevertheless, studies consistently showed a dominance

of nonforest invertebrate species in oil palm plantations (Danielsen *et al.*, 2008). On average, only 15% of vertebrate and invertebrate species recorded in primary forest could be found in oil palm plantations (Fitzherbert *et al.*, 2008). Not surprisingly, plant diversity within oil palm plantations was also impoverished compared with forests due to regular maintenance (e.g., weeding) of oil palm fields (Danielsen *et al.*, 2008; Fitzherbert *et al.*, 2008).

Climate Change and Forest Fires

Climate change impacts on biodiversity have been relatively mild compared with the other main threats in the last century. However, it is very likely that climate change will be one of the most dominant biodiversity threats this century (MEA, 2005). In particular, strong field evidence of climate change effects has been reported in the montane areas in Southeast Asia, where moth ranges have shifted to higher elevations in the last 42 years (e.g., Sabah, Malaysia; Chen *et al.*, 2009). In addition, recent reviews of the literature and guide books revealed that certain amphibians and reptiles, and birds, respectively, appear to be responding to global warming by shifting their elevational ranges upwards (Peh, 2007; Bickford *et al.*, 2010). Because Southeast Asia consists largely of islands with few mountain ranges, many affected island species may not be able to migrate or disperse under climate change (Bickford *et al.*, 2010). As a consequence, high elevational species may be adversely impacted by rapid climate change, indirectly affecting species assemblages and communities, and ecosystem functioning and services.

Forest fires in Southeast Asia can negatively impact species and alter communities. For example, Sumatran bird diversity declined with open field species replacing forest specialists (e.g., understory insectivores) over time (Adeney *et al.*, 2006). ENSO-induced wildfires in Borneo also reduced butterfly species richness significantly (Cleary *et al.*, 2003). Both studies suggest that wildfires have strong impacts on species communities in Southeast Asia. The two recent ENSO-induced wildfire episodes (i.e., 1982–83 and 1997–98) revealed the potential for destruction of high-intensity fires on forest biodiversity (Baker *et al.*, 2009; Page *et al.*, 2009). However, more critically, the changing fire regimes (increasing occurrence of large fires) due to both growing human pressures (through forest clearance) and projected climate change may further result in a huge loss of forest with severe impacts on biodiversity. They might also pose serious public health risks to the human populations in this region (Lohman *et al.*, 2007; Taylor, 2010). In essence, forest loss and fragmentation, and climate change, would lead to the edges of forest patches drying up, a regional drop in evapotranspiration rate, and large-scale shifts in rainfall due to a disruption of the Indian monsoon and ENSO cycle, all potentially enhancing fire risk and frequency, water loss, and thermal stress (Brook *et al.*, 2008). Together, the synergisms of these threats would place the biodiversity and people of Southeast Asia under grave danger. As such, large-scale and regionally coordinated fire management plans are urgently needed to mitigate the projected high-intensity and high-risk wildfires (Lohman *et al.*, 2007; Johnson and Dearden, 2009).

Overexploitation and Illegal Trade of Wildlife

Overexploitation of wildlife can cause irreversible loss of species and populations, ecosystem perturbations, economic loss, food shortages, and spread of pathogens. In the last 50 years, the need to hunt for subsistence in tropical Asia has been increasingly supplanted by the need to hunt for the market (Corlett, 2007) – this has led to population declines and local extirpation of threatened species in certain areas (Lee *et al.*, 2005; Phoonjampa and Brockelman, 2008). More charismatic threatened species (e.g., rhinos, elephants, and tigers; Clements *et al.*, 2010a), however, are increasingly being hunted to fuel the trade of illegal wildlife and their products (e.g., ingredients in traditional Chinese medicine; Figure 4). The illegal wildlife trade refers to the unlawful trade, smuggling, poaching, capture, or collection of endangered species or their parts (including animals or plants that are subject to harvest quotas and permit regulation; South and Wyatt, 2011).

Southeast Asia is now regarded as one of the world's largest illegal wildlife trading hubs, with almost every country serving as source and/or transit point to markets beyond the region (i.e., China being the largest market followed by the USA; Felbab-Brown, 2011). The value of this illicit market in this region was recently estimated to be worth around USD 10–30 million annually (Then, 2010; Felbab-Brown, 2011).

The Convention on International Trade in Endangered Species (CITES; www.cites.org), which is an international agreement among governments to ensure that the international trade of wildlife specimens does not threaten their survival, affords varying degrees of protection to more than 30,000 species of plants and animals. A nongovernmental organization (NGO) known as TRAFFIC (www.traffic.org) is involved in monitoring the legal and illegal trade of CITES species in Southeast Asia. Despite regulatory mechanisms such as CITES, large volumes of CITES-listed species permitted for trade continue to be exported illegally above set quotas (Nijman, 2010). Furthermore, species that are prohibited for international trade continue to be sought after by poachers due to the relatively low risk and high profitability of this business (Figure 5). Examples of wildlife being persecuted for the illegal trade in Southeast Asia include mammals

(e.g., bears, Shepherd and Nijman, 2007; elephants, Shepherd and Nijman, 2008; felids, Ng and Nemora, 2007; pangolins, Pantel and Chin, 2010; primates, Nijman, 2005; rhinos, Ahmad Zafrir *et al.*, 2011); reptiles (e.g., snakes, Auliya 2010; tortoises and turtles, Nijman and Shepherd, 2007); birds (Shepherd *et al.*, 2004); and plants (The World Bank, 2005).

Although legal and illegal hunting of species in this region is regulated to some extent by national wildlife laws, hunting quotas continue to be exceeded and hunting prohibitions may be ignored partly due to the lack of mechanisms in place to monitor population trends of species being hunted (Clements *et al.*, 2010a). The harsh reality is that enforcement systems in this region have largely failed to curb wildlife overexploitation, which is showing no sign of abating (Bennett, 2011; Figures 6 and 7).

Others: Invasive Species and Disease

Invasive species can be defined as exotic species that adversely affect environments they invade. In Southeast Asia, invasive species can cause the displacement of native biodiversity due to synergistic factors such as an invasive species' advantageous life-history traits (in certain plants and molluscs; Osunkoya *et al.*, 2005; Clements *et al.*, 2006), competition for similar resources (among birds; Huong and Sodhi, 1997), ecosystem modification (by plants and butterflies; Peters, 2001; Ghazoul, 2004), hybridization, environmental disturbance, and economic loss (Brook *et al.*, 2003). The Global Invasion Species Database (www.issg.org/database) contains the most comprehensive list of invasive species present in Southeast Asia. Indeed, every country in the region contains invasive species, with Indonesia harboring the highest number (78 species), and plants and fish being the most common invasive animal groups (Peh *et al.*, 2010). Continental islands such as Singapore appear to be the worst-case scenario for invasibility with alien species dominating persistently disturbed areas, but very few introduced species have successfully invaded closed-canopy forests (Corlett, 2010). However, in natural aquatic systems, the negative impacts of invasive species appear to be more pervasive (e.g., among fish; Nguyen and de Silva, 2006). Ecosystems that are subjected to increasing levels

Figure 4 One of Southeast Asia's endangered mammals, the Malayan tiger (*Panthera tigris*), photocaptured in a selectively logged forest in Malaysia. This charismatic species is being persecuted by illegal wildlife traders for products such as ingredients in traditional Chinese medicine.

Figure 5 A group of poachers caught on a camera trap trespassing into selectively logged forests from a highway in Malaysia. Their possession of a modified shotgun indicates that they are targeting endangered large mammals, possibly for the lucrative wildlife trade.

Figure 6 Agricultural expansion in the montane forests of Peninsular Malaysia has increased levels of siltation and chemicals in downstream water systems with negative effects on freshwater biodiversity.

of disturbance can also become more susceptible to the establishment of invasive species. For example, more disturbed peat swamps in Malaysia appear to be more prone to invasion by noxious weeds (Yule, 2010).

The transmission of diseases and pathogens that threaten Southeast Asia's biodiversity has undoubtedly been facilitated by globalization. One particular emerging disease of great concern to herpetologists is chytridiomycosis, a fatal

Figure 7 A LANDSAT 5 satellite image taken in August 2004 over Peninsular Malaysia showing an influx of sediments (red box) from upstream developments along the Kelantan River into the marine environment. Data available from the US Geological Survey.

amphibian-specific skin disease caused by a fungal pathogen *Batrachochytrium dendrobatidis*. Although this chytrid fungus has mainly been recorded in tropical regions outside Southeast Asia, it was recently recorded for the first time among amphibian species in Indonesia (Kusrini *et al.*, 2008). Commercial trade and invasive species represent the more likely vectors of pathogens, but large-scale mortality of native biota as a result of pathogens introduced from alien vectors are yet to manifest in this region (Peh, 2010). However, approximately 75% of human diseases having links with wildlife is of concern (Patz *et al.*, 2004). In Indonesia, for example, the risk of transmitting zoonotic diseases between fruit bats and humans appears to be high given the former is a carrier of Henipaviruses (Harrison *et al.*, 2011), which have caused numerous fatalities among animals and humans in Malaysia and Singapore (e.g., Nipah virus; Breed *et al.*, 2006). The deadly H5N1 influenza virus also remains a major threat to both humans and wild birds in this region. For example, this virus has been found in bar-headed geese that died *en masse* in certain areas of China after being infected; this species may pose a threat to native avifauna in the region as it migrates to aggregation and breeding grounds in Myanmar (Chen *et al.*, 2005).

Challenges and Opportunities

Enhance Protected Area Networks

Protected area networks represent one of our core strategies in biodiversity conservation and protection of ecosystem services (Chape *et al.*, 2005; Luck *et al.*, 2009). Reserves in Southeast Asia have been shown to be safe havens for butterflies, forest endemic birds and bats, for instance (Koh and Sodhi, 2004;

Lee *et al.*, 2007; Struebig *et al.*, 2010). In addition, protected areas can be effective in buffering against human encroachment such as deforestation (e.g., Myanmar, Songer *et al.*, 2009). However, these reserves are also under increasing threats from isolation due to extensive forest loss and degradation in areas surrounding them (DeFries *et al.*, 2005). Furthermore, reserves in Southeast Asia may only be “paper parks” that are poorly managed and suffer illegal logging (e.g., in Kalimantan, Indonesia; Curran *et al.*, 2004). The proportion of natural forest under protection across the countries is also relatively low (<10%), with nations like Myanmar and Vietnam having <5% of land area currently protected (Rao *et al.*, 2002; Sodhi *et al.*, 2010a). This is despite the fact that the region has the highest deforestation rate as well as the lowest remaining forest cover (Sodhi *et al.*, 2010a). Poverty and corruption may also be tied to higher incidence of fires in Southeast Asia parks (Wright *et al.*, 2007). Nevertheless, parks, if effective, have the potential to alleviate human poverty rates as recently demonstrated for Thailand (Andam *et al.*, 2010).

The future conservation battlegrounds are expected to shift under future climate and land-use changes (Lee and Jetz, 2008). In particular, Southeast Asia will continue to suffer heavy conversion pressure as global human populations and demand for agricultural products soar this century (Lee and Jetz, 2008). Much of the unprotected land is projected to be transformed into human-modified landscapes thus increasingly reducing the connectivity between reserves. This potentially hampers species dispersal, which may be the most serious in high-altitude sites where species may be pushed out of the reserve boundaries due to increasingly unsuitable climatic niches (Hannah *et al.*, 2007). In Thailand, for instance, the national protected area network has been assessed for the conservation of tropical forest butterflies using high resolution regional land-use and climate change projections (Klorvuttimontara *et al.*, 2011). Studies evaluating the effectiveness of reserves in protecting biodiversity under global change will be extremely valuable for future conservation planning and should be a priority in Southeast Asia. As such, it becomes particularly important and urgent to rapidly expand the reserve network of the region, considering projected change impacts; increasing connectivity among reserves; and improving park enforcement, governance, and management in order to combat impending global change.

Safeguard Biodiversity in Human-Dominated Landscapes

Well-enforced protected areas have demonstrated their effectiveness at preserving biodiversity in some countries (e.g., in the Philippines; Samoilys *et al.*, 2007). Improving the management of protected areas is therefore one of the most important strategies to safeguard biodiversity in human-dominated landscapes across the region; even a modest increase in funds can help improve their effectiveness (Bruner *et al.*, 2001). Community-based conservation within protected areas should also be explored as local collaborative programs can aid wildlife population recovery (e.g., in Thailand; Steinmetz *et al.*, 2010). Given that primary forests are irreplaceable in sustaining biodiversity (Gibson *et al.*, 2011), remaining tracts of primary forests with adequate habitat connectivity should be prioritized for protection (e.g., by

prohibiting road development; Laurance *et al.*, 2009) and gazetted as protected areas if possible.

Degraded habitats such as selectively logged forests must still be afforded greater protection as they are biologically important (Edwards *et al.*, 2011), supporting some of the world's most endangered species (e.g., the tiger *Panthera tigris*; Rayan and Shariff, 2009). Selectively logged forests of high conservation value should therefore be prioritized for improved sustainable management (Giam *et al.*, 2011a, b) and protected from conversion to commercial plantations (e.g., Aziz *et al.*, 2010), which should only be allowed to expand on preexisting cropland and degraded habitats (Koh and Wilcove, 2008). One mechanism through which selectively logged forests in Southeast Asia can be better protected is through the United Nations Framework Convention on Climate Change (UNFCCC) framework "REDD+" (UNFCCC, 2010). Although REDD schemes show great promise in protecting the region's imperiled biodiversity (e.g., for mammals in Indonesia; Venter *et al.*, 2009), and web-based decision-support tools are now available (Koh *et al.*, 2011a; available at www.REDDcalculator.com), many political, economic, and social challenges have to be overcome to ensure success (Butler *et al.*, 2009; Clements *et al.*, 2010b; Sanderbrook *et al.*, 2010).

To mitigate specific threats such as illegal hunting of threatened species in and around forests, NGOs have established antipoaching groups (Figure 8) in association with enforcement authorities to combat the threat of poaching (e.g., in Malaysia and Indonesia; Clements *et al.*, 2010a; Ahmad Zafir *et al.*, 2011). At a larger scale, regional governments are taking encouraging steps by improving outdated national wildlife laws (e.g., the Wildlife Conservation Act 2010 in Malaysia) and forming an intergovernmental wildlife enforcement network (asean-wen.org), which has had some success in clamping down on illegal wildlife traders (Lynam, 2010).

To better protect native fauna from invasive species, recommendations (in ascending order of gravity) would be: (1) prevention of their introduction entirely, (2) swift eradication of an incipient population, and (3) harnessing a combination of technologies to mitigate the threats from an established population (Corlett, 2010; Simberloff, 2010). Scientists that discover the presence of potentially invasive species should not only publish their findings as soon as possible, but also alert authorities to urgently implement appropriate control measures (e.g., Figure 9; Tan and Clements, 2011). Although zoos and gardens should be well equipped with strategies to minimize the risk of escape from invasive species (Dawson *et al.*, 2008), custom departments should adopt stricter quarantine measures for species arriving via the horticultural and pet trade, which are considered the main avenues for the arrival of invasive species (Corlett, 2010).

To deal with the threat of emerging infectious diseases (EIDs) to native biodiversity, control measures include: (1) minimizing contact with the direct host, (2) monitoring of intermediate hosts, (3) improving biosecurity on farms, and (4) better disease recognition and diagnosis (Field and Mackenzie, 2004). Studies aimed at identifying traits that predict the vulnerability of taxa to EIDs should be carried out well in advance of their declines as recovery of population crashes can be very difficult, if not, impossible (e.g., Bielby *et al.*, 2008). Regarding the threat of pollution, several

Figure 8 A ranger from the Rhino Protection Units (RPUs) of the Rhino Conservation Program in Indonesia, a good example of an antipoaching initiative formed by an NGO in collaboration with government authorities. RPUs not only conduct intelligence-driven patrols in protected areas trying to save the Sumatran Rhino from extinction, but they also help remove poaching threats to other endangered species. (Photo credit: Ahmad Zafir Abdul Wahab).

conventions have been signed to address the negative effects of marine pollution to biodiversity (see Todd *et al.*, 2010). A reduction in pollution from wildfires may be achieved through several priority actions (see Lohman *et al.*, 2007), especially through the enactment and enforcement of laws that prohibit further conversion of peatlands. For example, a 2-year moratorium on peatland conversion in Indonesia was passed in 2010 in return for monetary payments from the Norwegian government on successful implementation.

Despite some conservation successes at varying scales (Sodhi *et al.*, 2011), much more needs to be done (beyond the limits of this article) to safeguard biodiversity in human-dominated landscapes within Southeast Asia. Ultimately, biodiversity conservation requires greater political will and support from civil society, including industry, environmental groups, and the wider public (Clements *et al.*, 2010a; Bennett, 2011), without which there will be no halt to the current slide of the region's biodiversity toward extinction (Sodhi *et al.*, 2004).

Forest Restoration

Reversing these trends through forest restoration is attracting attention across the tropics (Braxton Little, 2008; Chazdon,

Figure 9 A potentially invasive snail, *Limicolaria flammea*, recently discovered in Singapore, possibly introduced from Africa via the horticultural trade. Scientists who discovered it alerted government authorities through letters and a publication, but political will to eradicate this species has been weak and reports now indicate that it has expanded its distribution.

2008; Normile, 2009; Lamb, 2011), motivated by the need to mitigate greenhouse gas emissions (Drummond *et al.*, 2010), restore key habitats for species of conservation concern, and enhance the biodiversity value of human-modified landscapes (Gardner *et al.*, 2009). For example, the restoration of logged-over forests in Sabah has resulted in more rapid recovery of insectivorous bird populations than in naturally regenerating logged forest (Edwards *et al.*, 2009).

Ecological Restoration programs will require, among other things, tree nurseries that have adequate stocks of seedlings of native tree species. Many of the larger tree species (particularly among the Dipterocarpaceae) reproduce during infrequent community-wide “general flowering” events (masting). The dipterocarps, which comprise 10% of tree species and 80% of canopy species on the island of Borneo, have recalcitrant seeds. These biological constraints present a major challenge to collection of seeds and seedlings that form the basis of forest restoration projects across dipterocarp-dominated lowland forest (Kettle *et al.*, 2011a, b).

The knowledge base for implementing successful forest restoration has grown over several decades of silvicultural and ecological research in tropical Asia (Adjers *et al.*, 1995; Kettle, 2010). Dissemination of the existing knowledge via Internet-based virtual networks of restoration projects would enhance knowledge transfer and technical capacity. Development of transboundary phenology monitoring programs will ensure that flowering and mast fruiting events are capitalized to their full advantage. The existing networks of botanical gardens and Forest Research Institutes should also play a substantial role in capacity building at the local and regional scales.

Appendix

List of Courses

1. Conservation Biology

2. Managing Ecosystems for Resistance and Resilience

3. MA in Conservation Biology

See also: Agriculture, Sustainable. Biodiversity in Logged and Managed Forests. Biodiversity-Rich Countries. Climate Change and Extinctions. Deforestation and Land Clearing. Endangered Amphibians. Endangered Ecosystems. Endangered Mammals. Endangered Plants. Endangered Reptiles. Endangered Terrestrial Invertebrates. Human Impact on Biodiversity, Overview. Land-Use Issues. Mangrove Ecosystems. River Ecosystems. Threatened Birds. Tropical Forest Regeneration

Glossary

Beta diversity Turnover of species within a small spatial scale resulting from highly differing ecological conditions.

Biogeographic regions Major areas of the world where large assemblages of species originated and that differ considerably from other regions.

Convention on Biodiversity (CBD) An international convention signed by 175 countries, which originated at the Earth Summit of Rio de Janeiro in 1992.

Cultural diversity Variation of races, languages, and habits including art that define a given culture.

Database Assemblage of information organized in tables with a logical structure. It is a fundamental tool used to gather, organize, and analyze biodiversity information.

Endemism Confinement of a species or other taxonomic groups to a given region, for example, an island or a country.

Megadiverse An area or a country possessing a much larger proportion of species than would be expected by its extent, latitudinal position, and other factors.

Parataxonomist Laymen and peasants trained to collect and carry out preliminary identification of botanical and zoological specimens. They are widely used by INBio in Costa Rica.

Phylum A major category, between kingdom and class, of taxonomic classification.

Primary production Amount of energy produced by photosynthetic organisms in a community.

Introduction

The fact that different countries harbor contrasting degrees of biological diversity has been recognized since the time of the great naturalists–travelers (including Darwin, Humboldt, Wallace, and others). More recently, the occurrence of biodiversity-rich countries has been described in more quantitative terms, under the notion of “megadiversity countries.” Conservationist Russell Mittermeier developed it with an initial emphasis on tropical primates. Later, it was extended to all types of ecosystems and several groups of organisms (Mittermeier *et al.*, 1997). The concept of megadiversity countries is also related to that of centers of diversity – species-rich areas with a high concentration of endemic organisms. However, the centers of diversity are naturally defined spatial units, whereas megadiversity countries are geopolitical entities. Not surprisingly, therefore, there is no precise numerical coincidence between centers of diversity and megadiverse countries. For instance, at the global scale, the Plant Conservation Office of the International Union for the Conservation of Nature (<http://www.iucn.org>) recognizes 234 centers of plant diversity, whereas the number of megadiverse countries, from the botanical point of view, is only approximately 10. However, some spatial overlap is observed: Of the total number of plant diversity centers, close to 50% are located within these 10 megadiversity countries. That such concentrations of the planet’s biodiversity are located in a handful of countries constitutes a matter of national, regional, and global importance.

Facets of Biodiversity in Biodiversity-Rich Countries

To examine the underlying causes for the concentration of biodiversity in specific countries, the authors first discuss the criteria on which the definition of megadiversity is based.

Consideration of species richness is the predominant approach in ranking areas according to their biodiversity. However, in this article, and following Mittermeier *et al.* (1997) and Dirzo and Raven (2003), megadiversity is defined on the basis of six facets of biological diversity.

Species Richness

The authors consider species richness of vascular plants and of the four major groups of animals for which knowledge is better: mammals, birds, amphibians, and reptiles. Species richness in these groups of organisms, and plant species in particular, can be taken as correlates of other lesser-known organisms, and as a surrogate of total species richness. When available, species richness of other groups of organisms is also used.

Concentration of Endemisms

The concentration of endemisms refers to the percentage of endemic species present among a country’s total resident species. This criterion is also based on the best-known groups of organisms: plants, mammals, birds, amphibians, and reptiles.

Ecological Heterogeneity and Diversity of Habitats

The diversity of habitats refers to the diversity of distinct ecological settings, usually expressed by the diversity of vegetation types. Closely related to this facet is the concept of beta diversity, the spatial turnover of species between nearby or adjacent habitats. Indeed, high beta diversity typically results from the heterogeneity of ecological conditions.

Presence of Tropical Forest Ecosystems

Given that tropical forests, particularly rain forests, are widely recognized as the most species-rich terrestrial ecosystem (Dirzo and Raven, 2003), their presence is used as another indicator of megadiversity.

Presence of Marine Ecosystems

The presence of marine ecosystems is included because they hold the greatest diversity of taxa of higher rank ("deep diversity"). In particular, marine ecosystems are rich in phyla of animals: 35 animal phyla are known from the sea, 14 of them being exclusively marine, whereas only 11 are terrestrial and only one exclusively so.

Cultural Diversity

The cultural diversity criterion addresses the diversity of ethnic groups present in a given country. Its relevance in diversity-rich countries stems from the strong association between biological diversity and cultural diversity. Different cultural dimensions in different countries have played a significant role in the modes in which the conjunction of biological diversity, including natural and domesticated biodiversity, is perceived, maintained, used, and valued by different ethnic groups.

Underlying Causes of Diversity in Biodiversity-Rich Countries

The predominant underlying causes that determine the existence of biodiversity-rich countries are latitudinal position, physical factors that increase primary production, historical (e.g., geological and tectonic) factors, environmental heterogeneity, and the presence of tropical rain forests. Most of the information regarding the relationship between these factors and biodiversity, however, considers species richness.

Latitudinal Location

Latitudinal location is not a determining factor of biodiversity per se. Rather, it is a proximal correlate of biodiversity: For

almost all groups of organisms, species diversity increases toward equatorial latitudes. For example, on land, species richness and latitude are negatively correlated among mammals, birds, and trees (Figure 1).

In consequence, countries located at lower latitudes tend to be rich in species of many groups. Table 1 shows the contrast between tropical and temperate countries in terms of the number of plant and mammal species. Regardless of size, the sample of countries located close to tropical latitudes has plant and mammal diversities that are about twice as large as those of the temperate countries sample. Although some temperate (e.g., US) or partly temperate (e.g., Australia) countries of large area reach values of species richness that are comparable to those of tropical countries, the tropical nations of this sample constitute a list of potential biodiversity-rich countries.

The pattern of decline in species richness with latitude in terrestrial ecosystems is paralleled in marine systems, although available information relates to other groups of organisms. For example, Arctic waters contain approximately 100 species of tunicates (sea squirts), temperate seas contain some 400 species, whereas waters at tropical latitudes have more than 600 species. Although data are not readily available for individual countries, the similarity of latitudinal patterns in terrestrial and marine systems suggests that a comparable trend exists on a per country basis, which again indicates that low-latitude countries are likely biodiversity-rich countries on the basis of marine species richness too. In sum, using the species richness criterion, biodiversity-rich countries are expected to be located in low-latitude regions of the world.

Physical Factors of the Environment Leading to Increased Primary Production

Consistently, primary production increases with precipitation, available solar energy, and nutrient availability (e.g., soil fertility). The highest terrestrial primary production is found in areas with high rainfall and year-round warm temperatures, whereas production decreases with lowered temperatures and the occurrence of frost. In marine settings, primary production increases with nutrient concentration, as is typical in some coastal zones, and it is lowest in open ocean, where nutrient

Figure 1 Latitudinal gradients of species richness for birds, trees, and mammals in North and Central America. Bars and numbers correspond to species richness according to latitudinal position on the map to the left. Table 1 Numbers of plant and mammal species in a selected sample of tropical and nontropical (mainly temperate) countries

<i>Tropical</i>	<i>Plants</i>	<i>Mammals</i>	<i>Temperate</i>	<i>Plants</i>	<i>Mammals</i>
Brazil	49,520–56,000	541–648	Argentina	10,000	338–374
Colombia	45,000–51,000	456	Australia	16,000–24,716	349–386
Congo Democratic Republic	11,000	430	Canada	2920	202
Ecuador	17,600–21,100	372–382	Egypt	2066	105
India	45,000	390–412	France	6000	123
Indonesia	37,000	670	Japan	4700	144
Malaysia	15,000	298	Morocco	7000	336
Mexico	30,000	450–535	South Africa	23,456	247
Peru	>20,000	467–508	UK	1550	77
Venezuela	15,000–21,000	363	USA	18,956	440

Source: Data derived from several sources, mainly National Reports for the Convention on Biological Diversity (CBD, 2009–2010), and IUCN Red List of Threatened Species (2010 Report, <http://www.iucnredlist.org>).

concentration becomes limiting. The relationship between productivity and biodiversity, however, is not always lineal. For example, in many ecosystems, species richness increases with the increment in primary production at low productivity levels, reaches a plateau at moderate levels of production, and then decreases at high levels of primary production. Thus, areas with environmental factors leading to increased primary production have, up to a certain level, a greater resource base that can support a wider range of species and typically have high species richness. As a result, countries with latitudinal and elevation ranges that include tropical and lowland regions, as well as coastal areas, where nutrient-rich waters up-well, tend to be megadiverse. Brazil, Peru, Colombia, and Mexico are clear examples of countries where such environmental conditions coincide.

Historical Factors

Historical factors are also critical in determining species richness and concentration of endemisms. Over a geological timescale, the continued rise in species richness is explained by the “provincialization” that accompanied the breakup of Pangaea and, later, Gondwanaland. Following their separation, evolution on each of the newly produced “provinces” (continents) produced many new taxa that were continental endemics and, indeed, much of the increase in species numbers of the Cenozoic era appears to be due to such continental isolation. As a consequence, several countries of South America (Brazil and Colombia), Africa (Democratic Republic of Congo), and Southeast Asia (Indonesia), are extremely rich in species, but they share few species in common because of their many millions of years of separation.

In general, areas that are geologically older have higher species richness than similar but younger areas, older areas having had more time to receive species dispersing from other regions of the world, and more time for existing taxa to undergo adaptive speciation in response to local conditions. The effect of geological age on species richness is well exemplified among marine ecosystems. The species richness of reef-forming corals is several times greater in the Indian Ocean and western Pacific than in the Caribbean Sea and adjacent Atlantic Ocean, which are considerably younger than the former. Similarly, mangrove ecosystems typically contain a

much higher number of arboreal mangrove species in the Old World than in the Neotropics. Marine species richness of countries associated with these older seas is therefore remarkably high, thus contributing to the existence of megadiverse countries in some of these areas. Australia is a clear example: Its Great Barrier Reef contains approximately 8% of the world’s fish species in just 0.1% of the global ocean surface area.

Regions rich in endemism tend to have experienced major events that caused fragmentation of the ranges of many species. Such fragmentation events leading to geographic isolation include continental drift, mountain building, and sea level changes. Subsequent to their isolation, taxa may undergo evolutionary radiation in a given locality. For example, isolation and subsequent evolutionary radiation due to continental drift have been fundamental to the generation of a high degree of endemism in the biota of Australia, Papua New Guinea, and Madagascar. Mountain building that led to isolation, explosive radiation, and a high accumulation of endemism is well represented in biodiversity-rich countries such as Colombia, Peru, and Mexico. Likewise, the remarkable diversity of fishes and other groups of organisms in large tropical lakes and rivers is due to rapid evolutionary radiation in such isolated and usually productive ecosystems, as exemplified by those aquatic ecosystems in Brazil, Colombia, and Peru.

As expected, islands often have high proportions of endemic taxa. Australia, a continent-island of remarkable size, is one of the world’s leaders in the endemism of mammals, birds, reptiles, and amphibians. Nevertheless, because islands frequently have a relatively depauperate biota, such high levels of endemism do not necessarily coincide with high richness of species, except on those islands where other driving factors are of exceptional importance, such as the large tropical archipelago of Indonesia.

Another aspect related to history is the distribution of floristic and faunistic assemblages of different geographic affinity, which define the so-called biogeographic regions or provinces, and reflect shared evolutionary histories and ecologies of species. The relevance of this aspect of biogeography lies in the fact that a few countries of the world are located at the meeting ground of adjacent biogeographic provinces. Three remarkable examples of this are the Nearctic and Neotropical regions that meet in Mexico, the Oriental and Palearctic regions in China, and the Indomalaysian and

Australoasiatic regions in Indonesia. The meeting points of biotas of different biogeographic affinity are so striking that, for example, on a single Mexican cloud forest site one can find gum trees and oaks, together with tropical trees, epiphytic cacti, and tree ferns among many other biogeographically different plant lineages.

A final aspect of historical nature is the magnitude of the coastal/marine contour in relation to land area. Overall, when this ratio is high, some components of biodiversity, including ecological diversity and species richness, tend to be high. Though coastlines and the presence of seas are common to many countries, the ratio is particularly high in islands and some countries that are rich in biodiversity (Table 2). Notable examples include Indonesia (an archipelago of several hundred islands), Australia, Madagascar, and Mexico. Table 2 shows that most of the megadiversity countries (cf. Mittermeier *et al.*, 1997) have coastline-to-area ratios that are relatively similar, with the exception of the Philippines and Indonesia, two countries constituted by archipelagoes, in which the ratios are exceptionally high. Mexico, in addition, includes extensive coastlines on two major oceans, the Pacific and Atlantic. Colombia is in a similar situation, although the ratio is lower. Mexico also has a sea of its own, the Sea of Cortez, all of which has resulted in significant levels of marine species richness, reflected by the fact that 51% of the marine mammal species of the world and close to 80% of all sea turtle species are present in Mexican coastal waters. It is worth noting that no land-locked country, regardless of its size, is a significant megadiversity country.

Ecological Heterogeneity

Species richness and the generation of endemism tend to be greater where there is significant ecological heterogeneity that allows for genetic isolation, local adaptation, and speciation to take place. Such situations can occur because of the existence of a series of isolated mountain peaks, large valleys, or drainage systems that become isolated and separated into smaller systems or areas that, being geologically heterogeneous and complex, produce a variety of soil conditions

with well-defined boundaries between them. In addition to the promotion of speciation, these situations may provide the necessary ecological heterogeneity on which a variety of communities can develop. This is reflected in two important – and related – aspects of the definition of biodiversity-rich countries: The occurrence of an ample diversity of vegetation types or ecosystems and the occurrence of a high turnover of species between adjacent localities, leading to a spatially structured diversity of species known as beta diversity.

Regarding the diversity of ecosystems and vegetation types, Colombia, Mexico, Indonesia, Peru, and India are remarkable in that their territories range from savannas and arid and semiarid ecosystems, to evergreen tropical ecosystems, and from coastal vegetation types (e.g., mangroves) to alpine and subalpine ecosystems. Brazil, in addition to its great predominance of tropical rain forests, includes other tropical vegetation types such as the semiarid cerrado and caatinga – two types of tropical dry forest.

Regarding species turnover, available data on individual countries are extremely limited. However, it can be inferred from the diversity of vegetation types and the magnitude of environmental heterogeneity that the countries that are prolific in these attributes are likely to have high levels of beta diversity. One illustrative case is Mexico, where tropical dry forests expand along a geographic gradient from approximately 15° to 26° N latitude in a variety of ecological conditions (Trejo and Dirzo, 2002). At a given locality within this range, the number of arboreal species (with 1.0 cm or greater diameter at breast height) per 0.1 ha is remarkably high, with an average of 75 ($N=20$ sites). However, the average proportion of species shared among sites is only 9%, implying that the turnover of tree species in biodiversity-rich countries is very high and that even a given vegetation type is composed of a series of distinct assemblages of species.

Presence of Tropical Rain Forests

Several of the determining factors of species richness and endemism discussed above are coincident in tropical rain forests and coral reefs (see Table 2). In particular, the presence of

Table 2 Presence of coral reefs and the relationship between a country's surface area and coastline for the twelve most important megadiversity countries defined by Mittermeier *et al.* (1997)

Country	Presence of coral reefs	Area (km ²)	Coastline (km)	Ratio coastline/area
India	Yes	3,287,590	7000	0.002
Philippines	No?	300,000	36,289	0.120
Madagascar	Yes	587,041	4828	0.008
Australia	Yes	7,741,220	25,760	0.003
Colombia	Yes	1,138,914	3208	0.002
Brazil	Yes	8,511,965	7491	0.0008
Mexico	Yes	1,958,201	11,592.77	0.005
Peru	No	1,285,215.6	2414	0.001
Venezuela	Yes	916,445	2800	0.003
Ecuador	Very small	275,800	2237	0.008
China	No	9,596,961	14,500	0.001
Indonesia	Yes	1,919,442	54,716	0.028

tropical rain forests is a significant indicator of the potential for a country to be in the biodiversity-rich group, given the compelling evidence that these forests are the most species rich compared to any other ecosystems (Dirzo and Raven, 2003).

Top Biodiversity-Rich Countries

The previous description gives some indication of the most likely nations to be considered biodiversity-rich countries. In their analysis of megadiversity countries, Mittermeier *et al.* (1997) examined 17 countries that collectively possess 66–75% of the planetary biodiversity (terrestrial, marine, and freshwater). However, not all of these examined countries comply with all the facets of biodiversity discussed here: Although some countries are prominent in one or more of those facets, they are not prominent in, or lack, some of them. A more quantitative analysis by the same authors led to a shorter list of countries based on a hierarchical scoring of the five most prominent values (scored from 1 to 5) for species richness and magnitude of endemism of plants, mammals, birds, reptiles, and amphibians. Additionally, even though information is much more limited, consideration was also given to freshwater fishes, butterflies, and tiger beetles (family Cicindelidae). Thus, a country that had the highest values of any of these components was assigned a score of 5, the second highest was given the score of 4, and so on. The total sum of these scores gave a value that could then be used to compare the different countries. For example, Brazil was highest in four components: species richness of plants, mammals, and freshwater fishes, and plant endemism (i.e., $5 + 5 + 5 + 5 = 20$). It also had three scores of 4 (species richness of amphibians = 12), four scores of 3 (species richness of birds and tiger beetles, and bird and tiger beetle endemism = 12), one score of 2 (bird endemism), and two scores of 1 (species richness and endemism of reptiles = 2). The total sum for Brazil is therefore 48. The corresponding values for the twelve most biodiversity-rich countries are shown in Figure 2.

This synthetic analysis confirms the suggestions of the previous sections and can be summarized as follows. Brazil is the most prominent biodiversity-rich country, followed by Indonesia and Colombia. At a considerable distance, Australia and Mexico follow in the fourth and fifth positions, respectively. The insular character of Madagascar highlights its outstanding endemism and places this country in the overall sixth place, close to Mexico. The other countries in Figure 2 are notable for their species richness (Peru, seventh position; China, eighth position; Ecuador, eleventh position; and Venezuela, twelfth position) or their degree of endemism (Philippines, ninth position). India is remarkable in both species richness and endemism, although it ranks in the tenth position. All seven of the most prominent diversity-rich countries share the following common biological attributes: (1) They have tropical rain forest ecosystems within their territories. (2) They also have marine ecosystems and, to a varying degree, a high coast-to-land ratio (see Table 2). (3) Their ecosystem diversity is considerable and therefore their beta diversity is expected to be high. (4) They have a very rich

Figure 2 The ranking of the twelve countries with highest biodiversity based on scores of species richness and endemism. Derived from Mittermeier RA, Goettsch-Mittermeier C, and Robles-Gil P (1997) *Megadiversidad: Los países Biológicamente más ricos del Mundo*. diversity of cultures. (5) They have considerable levels of threat to their biodiversity and cultural diversity, and (with the exception of Australia) all of them are developing countries. In particular, recent information on species of plants, birds, mammals, amphibians, and reptiles under several categories of extinction risk suggest that no less than 50% of the seriously threatened biological diversity at the global level is concentrated in the top megadiversity countries, as the authors discuss in the next section.

Threats to Biodiversity in Biodiversity-Rich Countries

These countries are experiencing significant alterations to their natural ecosystems, and such degradation is a serious threat to their biological resources. The main current threats to biodiversity in these countries are the current levels and patterns of land use that lead to severe deforestation, habitat fragmentation, and species overexploitation. Most of these countries are expected to be impacted, as well, by climatic change and the synergistic interactions of climatic change and other anthropogenic threats. An analysis of climate change and impacts on biodiversity-rich countries is out of the scope of this article, but given their immediacy, the authors focus on the effects of land use change and overexploitation.

Deforestation and Habitat Fragmentation

A commonly used metric of habitat destruction is the rate of deforestation. Table 3 presents FAO's compiled statistics on deforestation rates for the periods 1980–89 and 2000–10 (Food and Agriculture Organization (FAO), 2011). Rates of annual deforestation for the 12 biodiversity-rich countries in the previous decade ranged from 0.4% (Peru) to 2.3% (India and Ecuador). Only four countries had deforestation rates below 1% per year. Interestingly, in the period 2000–10, all biodiversity-rich countries showed a decline, in some cases

Table 3 Demographic, social, physical, and resource utilization parameters^a, including deforestation in megadiverse countries^b

Country	Population in 2010 ($\cdot 10^6$)	Growth Rate (1993–2000)	Rural population (% of total in 1993)	Area ($ha \cdot 10^6$)	Forested area (% of total)	Cultivated area (% of total)	Area under irrigation (% of total)	Firewood use ($m^3 \cdot 10^6$)	Yearly deforest. rate (%; 1980–1989; 2000–2010)
Brazil	195.4	0.7	23	851.2	57.3	4.9	6.7	194.27	0.7; 0.5
Indonesia	232.5	1.0	67	190.5	58.7	9.9	24.3	149.06	0.8; 0.5
Colombia	46.3	1.3	28	113.9	43.9	3.4	13.5	17.22	1.7; 0.2
Australia	21.5	1.0	10.9	771.3	18.8	6	4.6	–	–; 0.4
Mexico	110.6	0.9	22.2	195.8	24.9	11.8	26.3	1.3	1.3; 0.3
Ecuador	13.8	1.2	43	28.3	55	5.7	34.1	2.3	2.3; 1.8
Madagascar	17.3	3.2	74	58.7	39.5	4.4	42.1	1.2	1.2; 0.4
Peru	29.5	1.9	29	128.5	66	2.6	37.6	0.4	0.4; 0.2
Venezuela	29.0	1.5	8	91.2	32.9	3.5	5.9	0.7	0.7; 0.6
China	1354.1	0.6	71	956,100	13.5	9.6	53.6	220.6	–; 1.6
India	1214.5	1.3	74	328,759	20.8	50.5	28.9	262.8	2.3; 0.5
Philippines	93.6	1.7	48	30	45.3	18.4	28.6	35.98	1.5; 0.7

considerable, of the yearly deforestation rates. Even though these recent proportional figures seem low, for most countries these values represent a significant annual loss of absolute area and, potentially, a disturbance of long-term consequences, especially in light of the synergies between land use change and climatic change. In addition, rates of deforestation do not reflect the fact that the remaining areas of habitat frequently are left in the form of an archipelago of forest islands immersed in a matrix of transformed habitat. Forest fragmentation has been recognized as a significant factor leading to the local extinction of species, reduction of genetic variability, and disruption of several ecosystem processes and services.

Consistent with this decline in deforestation in the biodiversity-rich countries, worldwide deforestation has declined from *ca.* 10 million $ha \text{ year}^{-1}$ in the period 1980–99 to 7.13 million $ha \text{ year}^{-1}$ in the period 2000–10. Yet, we emphasize that habitat loss is still very large, particularly in some biodiversity-rich countries (e.g., Brazil). Habitat loss is recognized as the main driver of biological extinction, and botanist Peter Raven estimates that an average of 50,000 species may be lost per year during the next several decades, of which only some 7000 will have been recognized and named.

Overexploitation of Species

The overexploitation of species is much more difficult to document and no reliable, compiled statistics are available. Overexploitation of the majority of targeted marine fishes is very well documented, but this generally occurs in the “commons” of international waters. However, some isolated reports indicate that overexploitation is a significant threat to biodiversity in biodiversity-rich countries. For example, in the Brazilian Amazon, studies by zoologist Carlos Peres indicate that hunting of vertebrates (mammals and birds) can kill approximately 23 million animals per year. In summary, the great biological richness present in the biodiversity-rich countries is seriously threatened and urgent measures are needed to deal with this problem.

Socio-Demographic Characteristics and their Relation to Biodiversity

Of all the issues related to biological diversity, there are very few whose study makes any sense outside of the context of its relation with human populations. Indeed, human populations – their very existence, cultural evolution, size, and distributions – have been and still are intricately dependent and interactive with the biological diversity available to them in the regions where they live. Nowhere are these relations between population, cultures, and biological diversity more evident than in the majority of the biodiversity-rich countries, where the richest biological diversity is present, and where many of the ancient and most diverse human cultures and civilizations emerged. In many biodiversity-rich countries, indigenous groups comprise a high percentage of the population, commonly ranging from 10% to nearly 80% in the case of Papua New Guinea.

A measure of the cultural diversity of a country may be the number of languages spoken by its people. A total of 6700 languages are spoken in the world, and more than half are found in the 15 most biologically diverse countries (e.g., Papua New Guinea alone has more than 800 languages). This relationship between biological and cultural diversity – biocultural diversity – is explored by Víctor M. Toledo elsewhere in this Encyclopedia (Indigenous Peoples, Biodiversity and). Usually such a relationship has resulted in cultural traits and land use practices that have increased biological diversity, mostly through the development of new, cultivated species and their wild relatives. As illustrated in **Figure 3**, countries of both high biological and cultural diversity have generally been defined as centers of origin of crops, of management of wild biodiversity, and areas of development of agricultural technologies.

Rural Populations and Territorial Distribution

As **Table 3** shows, in stark contrast with economically developed regions of the world, most biodiversity-rich countries have increased their populations, and have growth rates that

Figure 3 Distribution of the twelve biodiversity-rich countries (shown in black), the centers of origin of crops (open circles), and centers of agricultural development (filled circles).

range from 0.6 (China) to 3.2 (Madagascar). They also have a considerable proportion of their total population living in rural areas (Table 3). Consistent with their relatively high coverage of forested area (with the notable exception of China; Table 3), these groups are highly dependent on biodiversity (e.g., firewood use; Table 3), and are usually deeply knowledgeable of its uses and ecological traits. Additionally, in many cases a large proportion of these peoples live in small villages, most of which are distributed within the high biodiversity regions in each country. Because of their close relationship with the surrounding environment and resources, most of these communities are intimately dependent on the conditions of the ecosystems in which they live for their quality of life and the maintenance of their well-being. They have been termed as “ecosystem people.”

Land Ownership by Indigenous Groups

The patterns of resource use and land ownership practiced by indigenous groups are normally the result of well-established traditions, forms of social organization, and consensus building. Communal land ownership is common, and it can take a variety of forms in different countries. Frequently, indigenous groups own or control extensive regions of natural forests and other ecosystems in these countries. For example, the indigenous groups in the Amazon basin possess more than 100 million ha of forested land. In Papua New Guinea, the many cultural groups that live therein own close to 97% of the national territory. In Mexico, nearly 75% of all the areas listed as priorities for conservation are under communal ownership (“ejidos”), mostly by indigenous or rural groups.

There is an abundant literature describing the benefits and disadvantages of communal land ownership in relation to the rational management and conservation of natural resources, particularly in biologically rich countries. After reviewing much of this literature and visiting the sites and talking to

people, it is apparent to the authors that when a strong and healthy system of internal governance exists, allowing participation of all interested parties, the community uses and conserves its resources in an admirable fashion (see an account of examples in Bray *et al.*, 2005). When those internal structures of governance break down for whatever reason, the communal system of land ownership may become as destructive of its resources as any other system.

Because of the often large indigenous population in an area, their widespread territorial distribution, and the patterns of land ownership, any program of biodiversity use and conservation in most of these countries must take these stakeholders into account. Such inclusion should not be undertaken as an unavoidable necessity, but rather as a wise approach to any conservation program. In addition to being the owners of the areas whose resources and services conservationists and governments wish to conserve, these indigenous groups typically possess an enormous wealth of valuable and ecologically informed knowledge, which is often the result of a long tradition of an orally transmitted culture from one generation to the next, and that makes them truly valuable partners in conservation, management, or restoration programs.

Although a great deal of traditional ecological knowledge exists among the indigenous groups of biodiversity-rich countries, the long-term sustainable use of many of those natural resources remains uncertain and difficult. This problem is caused by a number of factors, including rising pressure from growing populations to acquire land, increased demands for food production, and the actions of economic models and interests, often of foreign origin, that are likely to degrade or destroy biologically rich ecosystems.

Levels of Scientific Development

Another characteristic that is (deplorably) common to the majority of biodiversity-rich countries (with the sole exception

of Australia) is that they have a relatively incipient scientific infrastructure, which in many instances is reflected in the very small number of scientists (taxonomists, botanists, ecologists, etc.) that study their natural resources.

Although it is difficult to ascertain to what extent this is the result of the history of colonization – another important characteristic shared by all biodiversity-rich countries – they have in common that they have been dominated by a European country for diverse lengths of time, from a few decades to several centuries. In these cases, an appallingly poor effort was made by the European countries to promote the technical and scientific development of the colonies. Additionally, the subsequent development of these countries was characterized by a neglect of the traditional knowledge on natural resource management of their ethnic communities.

Very often the most important collections of flora and fauna of these countries are found in institutions, herbaria, and museums located in developed countries. This can play a significant role in limiting scientific training and consequently the national capacity to assess and manage natural resources. As described earlier, a great proportion of the planet's terrestrial biodiversity is located in tropical forests, and in general within countries that often lack the necessary scientific and institutional infrastructure. The authors believe that this is a major issue that must be addressed when considering the future of the conservation of the world's biological diversity. A discussion of this point is presented in the remainder of this article.

Human and Institutional Capacity for Biodiversity Knowledge and Conservation

With a few exceptions, a shared characteristic of the biodiversity-rich countries is that a very large proportion of the scientific collections that represent their biodiversity wealth are deposited in institutions located in diversity-poor but economically rich nations. Most of the vast collections of the Earth's biota (some 3 billion specimens, excluding micro-organisms) are located in the largest natural history museums and herbaria of the developed world, resulting from expeditions supported by developed countries during many decades, or even centuries. Many of these collections represent a heritage of significant historical value, since they contain biological information of regions that have been seriously altered and that presently have lost much of their original floras and faunas.

Much of the reason why these collections are not located in their "resident" countries is that only approximately 6% of the world's scientists live in the countries that house close to 75% of the planet's biodiversity. Different estimations coincide in calculating the number of taxonomists in the world to be approximately 7000. If a similar 6% ratio holds for taxonomists, this means that the biodiversity-rich countries have fewer than 500 taxonomists. We consider this to be an underestimation, and that there must be at least twice that number in the biodiversity-rich countries. However, even with this higher figure, this represents an inadequately small number of specialists who are able to adequately study an enormously rich biota.

Comprehensive and scientifically sound biological collections, together with the necessary taxonomic expertise that must go hand-in-hand with the collections, are a fundamental need to advance the ability of a country to know, understand, manage, and preserve its biological heritage. This was recognized at a high official level by the 175 signatories of the Convention on Biodiversity (CBD) during their fourth Conference of the Parties (COP) in Bratislava, Czech Republic, in May of 1998, who concluded that there exists what they called the "taxonomic impediment." This "impediment" results from the severe limitations of institutional and human infrastructure that affect the majority of biodiversity-rich countries. The very small number of taxonomists, systematists, and ecologists, as well as the absence, or very limited number, of zoological museums and herbaria that have reliable and long-term institutional support in most biodiversity-rich countries illustrates these limitations.

Table 4 is a compilation of the herbaria (with the number of specimens they contain), botanical gardens (with the number of taxa reported under cultivation), and zoological collections in the 12 most biologically diverse countries. It is clear that the majority have a serious shortage of scientific collections of their floras and faunas, with the notable exception of Australia and to a lesser extent India, China, and Indonesia in Asia and Brazil, Mexico, and Colombia in the Americas.

It is worth noting that for developed countries of the temperate regions the situation is dramatically different. The UK, France, and the US, for example, have between 10 and 100 times more herbaria and specimens housed in them than any of the 12 biodiversity-rich countries. The comparison is almost the same for zoological collections and botanical gardens. Obviously, only a fraction of those specimens belongs to their national floras and faunas, which makes them, together with a few other European countries like the Netherlands and Germany, the most important repositories of the biological information of the majority of biodiversity-rich countries.

At the Bratislava COP meeting, an agreement was reached on the imperative need to remove this "impediment" with the aim of fulfilling the objectives set by the CBD within a shorter period of time. However, the training of personnel at a high level, as is required for specialist taxonomists and systematists, and the extensive development of scientific collections (which in turn requires long-term institutional support) are complex, lengthy, and expensive processes. Most of the largest of such institutions in the world are the result of a tradition of many decades, and even centuries, of sustained institutional effort and economic support. This does not mean that those countries that do not have, or that need to develop more, such human and physical infrastructures should abandon any attempts to embark themselves in this process. Yet it seems to be far more effective to simultaneously dedicate efforts to develop a strong capacity to acquire, systematize, interpret, and utilize the biological information already existing in the many local and foreign museums and herbaria. Examples of such efforts, although not abundant, demonstrate different strategies in how to bridge the gap of knowledge about the biological diversity of a country. Some of these examples are presented next.

Table 4 Institutional infrastructure related to biodiversity in megadiverse countries

Country	Number of herbaria	Accessions in herbaria (10^6)	Number of botanical gardens	Number of taxa in botanical gardens (10^3)	Number of zoological collections
Brazil	88	3.2	23	17	18
Indonesia	6	1.67	5	70	3
Colombia	23	0.66	13	3	8
Australia	38	5.32	63	100	4
Mexico	52	2.3	35	7	25
Madagascar	2	0.08	2	5	2
Peru	11	0.45	6	–	3
China	306	15.5	68	27	7
Philippines	9	0.29	9	17	6
India	52	3.7	68	85	27
Ecuador	10	0.26	2	0.5	3
Venezuela	15	0.63	7	1	15

Case Studies of Managing Biological Information in Biodiversity-Rich Countries

As the authors have mentioned, by far the majority of the scientific information about the flora, fauna, and micro-organisms that live in a region or country is housed in the scientific collections of plants and animals. Such information is complemented to a certain degree by works such as written floras and faunas, updated checklists of organisms, and detailed ecological accounts of groups of plants or animals. However, only the scientific collections contain the wealth of information that covers the historical dimension of which organisms used to live in what now are profoundly disturbed areas. A second dimension, the geographical one, is also characteristic of scientific collections, found in the representation of specimens that records the spatial and ecological distribution of a species and its morphological and genetic variance within its range.

Despite the considerable wealth of information contained in most scientific collections, the access to such information has been essentially restricted to the scientists (taxonomists and systematists) who work on and take care of those collections. However, there has been an intense effort in assembling different catalogs and directories for biodiversity information in several developed countries. These mostly take the form of accounts of collections for diverse organisms, catalogs of described species, lists of endangered species, bibliographic sources, or environmental studies. Paradoxically, several of the best examples of development at the national level of the capacity to acquire, systematize, and utilize information about the biota of a country occur in some biodiversity-rich countries, as described next.

The Comisión Nacional Para el Conocimiento y Uso de la Biodiversidad (CONABIO)

CONABIO (<http://www.conabio.gob.mx>), of Mexico, was created in March 1992 as an interministerial organization with the mission of coordinating the actions and studies related to the knowledge and preservation of biological diversity, as well

as promoting and stimulating scientific research activities for the exploration, study, protection, and utilization of biological resources. Its aims are to preserve Mexico's ecosystems and to develop criteria for their sustainable management. Although CONABIO is placed within the Ministry of the Environment, and receives funding from federal sources, it operates with a private trust fund which allows CONABIO to obtain, in addition to federal funds, economic support from contracts, donations, and services, which help it to run a very efficient operation. The main functions of CONABIO are to: (1) Establish a national program for biological inventories. (2) Synthesize the information relating to biological resources in a permanently updated database. (3) Design and implement a National Biodiversity Information System. (4) Promote projects directed to the actual and potential use of biological resources that are both conventional and non-conventional. (5) Provide advice to decision makers in the government, civil society, and industry on technical and scientific aspects related to conservation and management of natural resources. (6) Produce educational materials for the general public, especially for younger people, and provide information about biological diversity and natural resources to all components of Mexican society. A recent effort of CONABIO has been a three-volume compilation on the ecosystems of Mexico, including a thorough account of known biodiversity of the country; a detailed assessment of the status and trajectories of change of Mexico's ecosystems, and a description of the national efforts to address the conservation and intelligent use of Mexico's "natural capital" (Sarukhán *et al.*, 2009).

In a period of only twenty years, CONABIO has become the central Mexican institution that compiles data and generates information on biodiversity and natural resources, and in so doing it has been able to bridge the gap between scientific research efforts and the production of information relevant to policy-making in the conservation of natural resources. One of its fundamental activities is the construction of a large, geo-referenced biodiversity database, developed with the participation of most of the taxonomic community of Mexico and also using the repatriation of information on Mexican

specimens housed in foreign herbaria and museums that hold large collections of specimens of Mexican organisms. Currently, these data are housed in various Mexican institutions, and are accessible to any interested person.

CONABIO does not conduct biological inventories or fieldwork on its own. Rather, it uses the biodiversity information already stored in national and foreign scientific institutions and funds a large part of the research carried out by Mexican scientists in the areas that have been identified as priorities in its mandate. The extensive program for the repatriation of data on Mexican species will continue over the coming years. The biodiversity database is constructed on the basis of the information contained in the label of each specimen included, which is taxonomically validated by experts in the different groups of organisms and then precisely geo-referenced. At present the database includes information on approximately 5.0 million specimens, and is constructed into a geographic information system (GIS) containing a wide array of data on climate, geology, topography, soils, vegetation types, land use patterns, and other factors.

The Environmental Resources Information Network (ERIN), Australia

ERIN (<http://www.erin.gov.au>) is Australia's oldest of all national entities devoted to compiling the biodiversity information of a country and building a database with that information. It has been a model and inspiration for other such systems around the world. The Australian government established it in 1989 as part of the Federal Department of the Environment. As is the case with CONABIO, ERIN's aim has been to provide biodiversity and environmental information to assist planning and decision making in the fields of conservation and natural resource management. It also draws information from many sources and institutions and its database is constructed on the basis of specimen information and compiled into a very rich GIS. ERIN is the main source for an array of fairly sophisticated data analyses about the distribution, conservation, and management of the Australian biota and serves to generate information for decision-making. It has become an increasingly powerful analysis tool for many studies of the biogeography and ecology of the country's plant and animal species and the assemblages and ecosystems that they constitute. It now covers subjects that range from endangered species to the effects of drought and pollution.

The Instituto Nacional de Biodiversidad (INBio), Costa Rica

Started in October 1989, INBio (<http://www.inbio.ac.cr>) has pioneered a substantial effort to survey the biodiversity of Costa Rica. It is a private, nonprofit organization, entitled to receive both governmental and private funds for its operation. Its Board of Directors and the General Assembly include representatives from different sectors of Costa Rican society who are stakeholders in the efforts to conserve the natural resources in the country.

One of INBio's central aims is to carry out a basic national biodiversity inventory. To this end, it has developed an active program of biological surveys of the major groups of

organisms and is building scientific collections of the different groups. This effort has involved the deployment of a substantial number of field assistants (mostly laymen and peasants) who are qualified as "parataxonomists" and who do most of the collecting of specimens and the initial taxonomic identification. INBio currently maintains a biodiversity database that provides geo-referenced information (by latitude-longitude), particularly of the specimens that have been collected since it started operating. Another of its stated aims is to support biodiversity conservation and promote new opportunities for sustainable development within the social and economic contexts of Costa Rica. It has also developed an important public education program on the subject.

A third area of INBio activity has been the prospecting for natural products in plants and animals of Costa Rica, which has been an especially active component within its various programs. The organization has a close collaboration with different governmental agencies in charge of the conservation and management of natural resources, and it has served as a constant source of advice and information to them in their programs.

The South African Botanical Diversity Network (SANBI)

SANBI (<http://www.ckw@nbipre.nbiac.za>) originated in the early 1990s as a multinational program closely linked to the National Botanical Institute (NBI) of South Africa; it was then called SABONET. It has now evolved into a very active institution with a mission to strengthen the level of biological expertise in the country, expand and improve scientific collections, and stimulate closer collaborative links among botanists and zoologists of the 10 countries that form the South African region.

The main objective of SANBI is "exploring, revealing, celebrating, and championing biodiversity for the benefit and enjoyment of South African people." SANBI is also responsible for ensuring that biodiversity knowledge influences policy, management, and decision-making. The three main areas of research of SANBI are biosystematics research and biodiversity collections, applied biodiversity research, and climate change and bio-adaptation. SANBI offers training courses and workshops to enable better environmental management practices and human capital development. It also organizes botanical expeditions to poorly known areas of the region, and publishes a newsletter. SANBI's homepage contains an ample description of its research and education programs.

Biota-Fapesp

Established in 1999, and conceived as a virtual Biodiversity Institute, this Brazilian organization (www.biota.org.br) deals with the biological diversity only of the State of São Paulo. It aims at characterizing and inventorying the biodiversity of the State, defining mechanisms for its conservation, assessing its economic potential and its sustainable use. Like other similar institutions, it aims at attaining information that can be useful for decision making in relation to the use and management of biodiversity, as well as in sharing freely and amply all the information gathered.

Sistema Nacional de Datos Biológicos (SNDB), Argentina

The SNDB (www.datosbiologicos.mincyt.gov.ar) is the national Argentinian organization dedicated to the compilation of biodiversity information of the country. Established in 2009, it is part of the Ministry of Science, Technology, and Productive Innovation. Its mission is “to assemble a unified database on biological information, based on taxonomic, ecological, cartographic, bibliographic, and ethnobiological data, also comprising catalogs on the use of natural resources and related subjects.” The system has a central node and several institutional nodes; it is built by 99 scientific collections housed in 24 institutions. Several of the collections also contribute to a variety of entities such as the Global Biodiversity Information Facility and the Inter American Biodiversity Information Network. The SNDB supports research proposals of the institutions that form part of it.

National Biodiversity Authority (NBA), India

Established by the Government of India, in 2003, the NBA (www.nbaindia.org) has as its functions to advise the government on matters related to the conservation of biodiversity, sustainable use of its components and equitable sharing of benefits arising from the utilization of biological resources. It also regulates activities and issues guidelines for access to biological resources. In stark contrast with similar organizations in other countries, the NBA in India possesses regulatory capacities.

Instituto de Investigación de Recursos Biológicos Alexander von Humboldt, Colombia

Instituted in 1995, in Colombia, the Humboldt Institute (www.humboldt.org.co/avh) has the mission of “promoting, coordinating, and conducting research that contributes to the knowledge, conservation, and sustainable use of biodiversity as a factor of development and well-being of Colombian society.” A civil corporation linked to the Ministry of the Environment, its mandate is to carry out scientific research on the biodiversity of the country. It is also responsible for conducting the National Biodiversity System, in coordination with close to 100 Colombian institutions, and for developing the country’s national biodiversity inventory. A section of the Institute studies the territorial and historic processes linked to the way in which use, transformation, and maintenance of biodiversity takes place. The Institute also has undertaken, in collaboration with IUCN, the task of producing red book lists of the threatened species of Colombia.

Conclusions

The world’s biological riches are unevenly distributed across the continents, and this distribution coincides with the same areas where many ancient and diverse cultures developed. These areas of high biological diversity now face threats not only from the activities and growing demand for natural resources of today’s much larger native populations, but also from demands that originate in distant, developed countries. Presently, these resources and ecosystems are under direct and imminent threat. Yet we now have a more complete understanding of these

ecologically diverse systems and the impacts of human activities on them on local, regional, and global scales.

Biodiversity-rich countries find themselves pressed between the responsibility, and even the fundamental desire, to preserve their biological diversity and the inescapable need to attend to the living requirements and well-being of their growing populations. The difficulty lies in meeting both the justified demands for development and increased well-being, and the responsibility for the conservation of those countries’ natural capital. We believe that in order for these countries to increase the possibilities of having a successful outcome in this apparent and not justified contention, serious consideration should be given to the following two points.

1. It is impossible to make informed decisions about the conservation of a country’s biological diversity if a scientifically sound platform of information does not exist. Such a platform is built with the training of specialists (taxonomists, systematists, ecologists, social scientists, etc.), the funding of extensive fieldwork, and the buildup of scientific collections or of information on the biological diversity of a country. These are long-term (many decades long) enterprises that should be undertaken in a carefully planned manner. Although these efforts are under way, a much faster and efficient way to collect and analyze information is to generate biodiversity databases using new field data and the vast amounts of existing information in herbaria and museums – all incorporated into an accessible GIS format. The authors believe that the examples discussed here for some countries offer an array of models that can be followed by other biodiversity-rich countries to enable them to better understand the extent and characteristics of their biological wealth.
2. In biodiversity-rich countries with large indigenous or rural populations, the conservation of biological diversity will require an honest and equitable collaboration with the owners of the resources (indigenous people or rural communities) that are the object of conservation or management plans. If this is not done beginning with the initial stages of planning, there will be limited success, if any, in such efforts. However, by carrying out successful collaborative programs using this approach, it will be possible to conserve a nation’s biodiversity and the cultures, languages, and traditions of the indigenous peoples who own and inhabit the land. Sustained efforts toward achieving this type of partnership for conservation of biocultural diversity in biodiversity-rich countries will pay off in the long run. Very simply, this “experiment” has seldom been done correctly and, once proven practicable and successful, it could then be adapted and applied to a variety of social, economic, and biological situations.

Glossary

Anion Negatively charged atom or molecule.

Cation Positively charged atom or molecule.

Chemoautotroph Capable of growing on inorganic substrates without light energy.

Eolian Wind blown.

Felsic rock Continental crustal rocks relatively rich in silicon and aluminum.

Fixation To make nonvolatile (forming organic molecules from inorganic gases).

Heterotroph Growth dependent on the oxidation of organic matter.

Mafic rock Oceanic crustal rocks relatively rich in magnesium and iron.

Orogenesis Formation of mountains.

Photoautotroph Growth dependent on the conversion of light to chemical energy (photosynthetic).

Spallation Thermally induced neutron and proton ejection following high-energy proton collision.

Introduction

Like life itself, biogeochemical cycles are far from thermodynamic equilibrium, have evolved over hundreds of millions of years, and are interdependent, forming biogeochemical systems replete with feedback controls (Schlesinger, 1997). Biogeochemical cycles depend on, and co-evolved with, specific metabolic pathways. Hence, biogeochemical cycles depend on and are a selective force in metabolic (i.e., biological) diversity. Over geological time, biogeochemical cycles are responsible for altering the chemistry of the ocean, atmosphere, and terrestrial ecosystems such that rate-limiting reactions within key cycles modify the tempo and mode of evolution. Here, we examine some of the key biogeochemical cycles in the context of their evolution and biological diversity.

The Distribution of Elements on Earth

The Origin of the Elements

The relative abundance of the crustal elements reveals a distribution of much more abundant light elements to lesser abundant heavier elements (Figure 1). Although the two lightest elements, H and He, were formed approximately 16 billion years ago in the “big bang,” all the heavier elements result from fusion of ^2He nuclei or fusion/spallation (proton or neutron loss) reactions in stars (Degens, 1989). The fusion reactions involving ^2He with itself, H, O, C, or N tend to form even-numbered atomic nuclei, whereas spallation and proton capture leads to odd-numbered nuclei. Additionally, because the nuclei of elements with paired protons are slightly more stable than those with an odd number, there is generally a larger relative abundance of even-numbered elements.

In the origin of our solar system approximately 4.6 billion years ago, elemental composition and planetary accretion were strongly influenced by the gravitational forces of the sun. Planet bodies closer to the sun contain relatively higher

proportions of heavy elements than bodies further away. The four innermost planets are approximately three times denser than the outer planets and have solid-rock surfaces that contain a relatively high proportion of metals, especially iron and aluminum. In the accretion process, a further gravitational distillation occurred within the planets. On Earth, the abundant heavier elements, such as nickel and iron, tended to migrate toward the center of the internal gravitational field, whereas lighter elements tended to float above the metal core and, upon cooling, accumulated as a solid surface and crust. The lightest elements formed a gaseous phase. Almost all of the two lightest gases, H_2 and He, escaped the gravitational field and diffused into interplanetary space during this initial period of Earth’s history.

The composition of the gases in Earth’s atmosphere following accretion is not completely resolved but almost certainly contained high concentrations of CO_2 , N_2 , and H_2O , HCl, and H_2SO_4 . This gas composition is similar to that currently on Venus. Precipitation of minerals and formation of felsic rocks led to the condensation and upward migration of liquid, precipitable water that overlies vast regions of denser, mafic rocks. Additional water may have been provided by meteoritic bombardment. Based on thermodynamic equilibrium calculations with crustal elements, the acidic gases or hydrated equivalents (e.g., HCl and H_2SO_4) would have solubilized mineral cations in the primordial ocean leading to a seawater dominated by Na^+ , K^+ , Mg^{2+} , and Ca^{2+} . The anion balance would have been supplied by vulcanism and outgassing from deep crustal sources. The dominant anions were Cl^- and, to a lesser extent, SO_4^{2-} and HCO_3^- . PO_4^{2-} was probably present but to a lesser extent, and fixed inorganic N (as NH_3 or NO_3) was almost certainly very scarce. The pH of the early oceans was probably close to neutral or slightly acidic (6.8–7.0). Additionally, radiogenically produced heat, the high concentrations of greenhouse gases, and geothermal activity would have provided a source of heat to maintain elevated temperatures in Earth’s early ocean history.

Figure 1 Relative abundances of the elements in the universe (based on log abundance of Si = 6). •, even atomic numbers; ○, odd atomic numbers. From these conditions, life arose and evolved. Over the course of Earth's history, there has been a continuous trajectory from the mildly reducing conditions that prevailed at the time of origin of the planet to the highly oxidizing conditions that prevail in the contemporary geological epoch. This oxidation trajectory is driven by biological processes but has also led to the increased diversity of life forms.

Phase State Transitions and Elemental Partitioning

The distribution of elements between the atmosphere, lithosphere, and hydrosphere depends, to first order, on the phase state of the element, its chemical reactivity, and its partitioning coefficients between water, the atmosphere, and the lithosphere (Table 1). Gases such as N_2 and O_2 partition between the atmosphere and liquid phase according to the solubility coefficient. CO_2 , H_2S , and NO_2 undergo hydration to form carbonic, sulfuric, and nitric acids. These acids deprotonate, according to the pH of the aqueous environment, forming anions. Consequently, the total solubility of these species in the aqueous phase exceeds that predicted from the vapor pressure alone, assuming the gases are chemically inert and obey idealized gas laws. Similarly, the distribution of elements between the aqueous phase and the lithosphere is dictated, to first order, by the solubility coefficient of the element, its reactivity or ionic form, and the saturation level. For example, all the alkali and alkali earth metals (i.e., Li, Na, K, Cs, Ca, and Mg) are highly reactive with water and are highly soluble. Precipitation reactions of alkali earth metal cations with carbonate, sulfate, or phosphate anions result in mineral deposits

in the solid phase. The movement of elements between the lithosphere, atmosphere, and hydrosphere is mediated by both purely physical/chemical processes and biological processes.

Physical/Chemical Transport Processes: Weathering

The flux of elements from continental rock sources to the atmosphere and oceans is promoted by weathering, which is the physical and chemical degradation of rocks to smaller physical pieces and soluble chemical constituents. The physical processes that promote weathering include erosion by water and wind, cracking through freeze-thaw cycles, and active abrasion by the movement of ice (e.g., glaciers), other rock formations (e.g., earthquakes and tectonic uplifting), or rocks (e.g., tidal abrasion). Ultimately, these processes lead to the formation of sediments that are transported by rivers to the ocean. In addition to physical weathering, chemical weathering is promoted by weak acids (e.g., carbonic and sulfuric) in precipitation as well as microbial and plant growth. Over geological time, the weak acids in precipitation remove alkaline cations, such as Mg and Ca, from carbonates and silicates, leading to the mobilization of these elements. Moreover, the production of weak organic acids by lichens, terrestrial plant roots, and the microbial degradation of decaying organic matter greatly promote chemical weathering. Thus, the invasion of land by terrestrial plants led to increased mobility of numerous elements and enhanced the fluxes of materials to the oceans. This results in a feedback between biogeochemical processes on land and in the ocean.

Table 1 Major chemical constituents of the Earth's Crust, Sediments, Ocean Water, and Atmosphere^a

Element	Crystal ionic charge and radius		Continental crust		Oceanic crust		Average sediments		Ocean water		Atmosphere

^aAdapted from Lerman A (1979) *Geochemical Processes Water and Sediment Environments*. New York: John Wiley & Sons.

The Hydrological Cycle

Weathering is strongly dependent on the hydrological cycle, which is one of the earliest and most critical cycles on Earth. Water is both a solvent and a vehicle for the transport of elements. It is also critically necessary for life. Hence, the distribution of biota is critically related to the availability of water. By far, the oceans are the largest reservoir of water on Earth (Figure 2). Flux of water into and from the oceans is driven by evaporation and precipitation, processes that are in turn driven by the heat budget of the planet. Over the oceans, evaporation exceeds precipitation; the net difference leads to precipitation over land. Because precipitation exceeds evaporation over land, there is a flux of water from land to the oceans in rivers. The atmospheric lifetime of water is extremely short—on the order of ca. 10 days. This lifetime compares with the average for the oceans of ca. 3000 years, whereas deep ground water can have lifetimes exceeding 10,000 years. These differences in lifetimes are critical determinants of fluxes of elements and climate feedbacks.

Vulcanism and Orogenesis

The riverine and eolian (wind-blown) transport of sediments from land to the oceans would, over geological time, erode the continents to the peneplane—the lowest level achievable. Vulcanism and other orogenic processes counterbalance erosion and supply new crustal rock and atmospheric sources of minerals. In the subduction regions of converging tectonic plates, sedimentary rocks are injected back into the deeper crust, where they are reprocessed by heat and pressure, emerging again in uplifting regions and through volcanic eruptions. In addition to the formation of igneous rock, vulcanism provides significant sources of iron, sulfate, and CO₂ to the atmosphere. These elements and materials are

transported through the atmosphere and deposited over both the oceans and on land.

Biological Transport

Biological processes influence the distribution of elements primarily through phase state transitions. The chemical reduction of inorganic carbon to organic matter is a conversion of a gas to solid phase; the latter is often dissolved in an aqueous phase of the cell cytoplasm. For oxygenic photoautotrophs, the evolution of molecular oxygen leads to the formation of a gas from the liquid phase of water. Biological mediation of phase state transitions is critical for the movement of elements between the atmosphere, lithosphere, and hydrosphere. For example, CaCO₃ is by far the largest reservoir of carbon on Earth (Table 2). The formation of CaCO₃ is the consequence of the biological precipitation by marine organisms and, over geological time, represents an important sink for atmospheric CO₂. The oxidation of organic matter leads to the formation of CO₂, which equilibrates with the atmosphere. Similarly, the biologically catalyzed oxidation of H₂S to S or SO₄ is a phase state transition that influences the partitioning of sulfur between aquatic ecosystems and the atmosphere. It should be noted that the biologically catalyzed phase state transitions need not be direct but can result from the indirect modification of the redox state of the environment. For example, the oxidation of H₂S occurs spontaneously in the presence of O₂; however, the O₂ is formed from oxygenic photoautotrophs.

Biological Assimilation

To accomplish phase state transitions, biological processes catalyze chemical and/or physical reactions. Reaction sequences require an assimilation of the elements. The

Figure 2 Estimates of the global water cycle and its reserves. The accuracy of several of its components is poor, resulting in a closure error for the whole cycle of about a factor of 2. The obvious interactive nature of the cycle makes it impossible to reduce current closure errors without studying the whole cycle. Reprinted from Chahine M (1992) The hydrological cycle and its influence on climate. *Nature* 359: 373–380.

Table 2 Carbon pools in the major reservoirs on Earth^a

Pools	Quantity ($\times 10^{15} \text{ g}$)
Atmosphere	720
Oceans	38,400
Total inorganic	37,400
Surface layer	670
Deep layer	36,730
Total organic	1,000

elemental composition of organisms is dictated, to first order, by the biochemical machinery required for maintenance, growth, mobility, reproduction, and defenses against predation. The four fundamental biochemical constituents that comprise all organisms, namely, proteins, nucleic acids, lipids, and carbohydrates, are primarily synthesized from six light elements: H, C, N, O, P, and S. Of these, N, C, and O are generally reduced, P is oxidized, and S can be both reduced

and oxidized. These six elements comprise approximately 98% of all living biomass. The remainder consists of approximately 20 ion-forming elements, including Na, Mg, Si, Cl, Ca, V, C, Mn, Fe, Co, Ni, Cu, Zn, Se, Mo, Sn, and I. The transition metals are frequently used in the mediation of electron transfer (redox) reactions.

Key Biogeochemical Reactions and Cycles

Hydrolysis and Oxidation-Reduction Reactions

Two biologically mediated chemical reactions are key to understanding biogeochemical cycles, namely, hydrolysis and oxidation-reduction processes. Hydrolytic reactions chemically remove from or add water to specific elements or molecules; the reactions are almost always accompanied by the transfer of protons and thus are pH-dependent processes. Hydrolytic reactions can be described in a general form by

Hydration/dehydration reactions can thermodynamically store or discharge energy and determine the reactivity and solubility of elements in the first series (H, Li, Na, etc.) and of phosphorous, (inorganic) carbon, and silica in the environment.

Redox reactions are characterized by the addition or loss of electrons, hydrogen atoms (but not simply a proton), or molecular oxygen. Redox reactions are the primary engines of life, and the consequences of redox chemistry strongly impact

the distributions of oxygen, carbon, nitrogen, sulfur, and transition metals in the environment. Redox reactions are always paired; there must be an oxidant and a reductant. The reaction process can be generalized by half-cells:

where the overall reaction is

For each half-cell, the tendency for a substrate to be oxidized or reduced is described by the Nernst equation:

$$E = (E_o + 2.3 RT)/(nF \log_{10}[A_{ox}]/[A_{red}])$$

where E is the redox potential (in volts), E_o is an arbitrarily accepted standard redox potential, F is the Faraday's constant ($= 96,487 \text{ C} = 1 \text{ mol electrons}$), n is the number of moles of electrons (Faraday's) transferred in the half-cell reaction, R is the Boltzmann gas constant, T is temperature in Kelvin, and A_{ox} and A_{red} are the activities (or more commonly the concentrations) of the oxidized and reduced forms of the molecules, respectively. The Nernst equation describes the equilibrium condition for both electronic and ionic processes.

To maintain perpetual redox reactions, reductants consumed in one reaction must be regenerated in another (Table 3). Hence, by the very fact that redox reactions are paired, a cycle is potentiated. However, to sustain a cycle of redox chemistry requires an input of energy (e.g., solar or thermal) that can be used to drive the initial condition far

from thermodynamic equilibrium. Biological reduction of inorganic carbon is one such process.

Fundamental Biogeochemical Processes Related to Carbon

The biogeochemistry of carbon is regulated by both hydrolytic and redox reactions. On geological time-scales (> 1 million years), the concentration of CO_2 in the atmosphere is a balance between crustal outgassing primarily through vulcanism which provides a source of CO_2 to the atmosphere, and chemical weathering of silica-rich rocks on the earth's surface. These reactions can be simplified as

The weathering process is stimulated by the hydration of CO_2 in the atmosphere in rain, forming carbonic acid. This is a self-limiting cycle; as CO_2 rises, weathering accelerates leading to a depletion of the atmospheric inventory, which reduces weathering. In the oceans there is an excess of Ca^{2+} , and an equilibrium in the inorganic carbon system is reached. This reaction series can be specified as

and

Note that the precipitation of CaCO_3 leads to the formation of CO_2 . In the absence of any biological activity, the geochemical processes would lead to a cycle of inorganic carbon between the three major reservoirs, namely, the atmosphere, oceans, and continents; however, biological processes interact in two critical ways to affect carbon chemistry. First, biological pathways lead to the reduction and oxidation of carbon. Photochemical and chemoautotrophic organisms oxidize alternative substrates to reduce carbon to the equivalent of carbohydrate. These reactions can be broadly classified in the reaction sequence

where A can be sulfur, oxygen, or organic compounds. This is an example of redox reactions applied to the formation of organic material.

Under mildly reducing conditions, photosynthetic carbon fixation is catalyzed by bacteria that couple the oxidation of H_2S or organic compounds to the reduction of CO_2 to form organic compounds. The thermodynamic energy gradient in such systems is relatively low, requiring inputs of $\sim 0.4 \text{ eV}$ of photon energy. Such energy demands are satisfied in the infrared spectrum.

Biominingalization and its Biogeochemical Inferences

Many organisms precipitate carbonates, phosphates, or silicates to produce minerals. In the marine environment, the precipitation of CaCO_3 by phytoplankton, corals, and several genera of marine invertebrates leads to the formation of aragonite and calcite, two forms of carbonate that are relatively resistant to degradation. Virtually all the carbonate

precipitated on Earth is the consequence of biological mineralization in the ocean. Over geological time, the production of carbonates produced vast beds of chalk, limestones, and marbles. The deposition of carbonates accounts for the largest reservoir of carbon on Earth. The isotopic fractionation of the stable isotopes of oxygen (^{18}O and ^{16}O) in carbonate sediments is strongly influenced by the temperature of the ocean when and where the carbonates are formed. The isotopic fractionation of the stable isotopes of carbon (^{13}C and ^{12}C) is related to the atmospheric/oceanic inventory of CO_2 . Hence, isotopic analyses of carbonates provide clues about both oceanic temperatures and carbon dioxide concentrations over geological time (Figure 3).

Some groups of marine planktonic organisms, including diatoms and radiolaria, as well as several genera of higher plant grasses, precipitate silica to form hydrated opal. Silica is supplied to the oceans from the weathering of continental rocks and the subsequent flux of soluble silicic acid via rivers. Like carbonates, the precipitation of silicates over geological time leads to sedimentary deposits. In terrestrial ecosystems, several groups of higher plants incorporate silica from soils into stems and shoots.

Under basic conditions, calcium and phosphate ions will spontaneously precipitate to form apatites, which are often mined as a source of phosphate for fertilizers and chemical feedstock. Vertebrates biologically control the precipitation of calcium phosphate to form bones and teeth. Approximately

85% of the phosphate and 95% of the calcium assimilated by vertebrates is incorporated in bones. The fossil record of these biomineral components provides a significant signature of vertebrate evolution but is not a significant component of crustal minerals.

The Oxygen Cycle

One of the most important characteristics of Earth's atmosphere is the relatively high concentration of free molecular oxygen (O_2). The mere presence of high concentrations of free molecular oxygen suggests that the chemistry of the planet is far from thermodynamic equilibrium. For all practical purposes, all the oxygen in the atmosphere originated from the photosynthetically mediated oxidation of water by oxygenic photoautotrophs. The oxidation of water to form free oxygen requires an oxidant with a potential of at least 0.83 V at pH 7. The bacterial photosynthetic apparatus could not achieve such a high oxidation potential without evolutionary modification. These modifications included the incorporation of Mn as the transient electron acceptor in the photosynthetic reaction center, the alteration of proteins that permitted the oxidation of water, and the raising of the potential of the primary electron donor by ~ 0.4 V. The latter was achieved by altering the pigment involved in the photosynthetic reaction from the relatively low energy levels that characterize bacteriochlorophylls to the higher energy levels found in chlorophyll *a*, a pigment that distinguishes cyanobacteria (i.e., blue-green algae) from all other photosynthetic bacteria.

The cyanobacteria are the oldest extant oxygenic photoautotrophs. The exact timing of the origin of cyanobacteria is uncertain, but micropaleological evidence suggests that organisms with features remarkably similar to those of modern cyanobacteria existed in the Archean ocean at least 3.5 billion years before present. Based on geochemical evidence (primarily the oxidation of iron by molecular oxygen), it appears that oxidation of Earth's atmosphere occurred over a relatively short interval of ~ 100 million years, beginning ~ 2.2 billion years before present (Figure 4).

Prior to the photosynthetic production of oxygen, all heterotrophic organisms oxidized organic carbon under anaerobic conditions. The biochemical oxidation of carbon under such conditions is thermodynamically inefficient, often leading to fermentation. For example, in the absence of oxygen, molecules such as acetate are potentially oxidized to methane and CO_2 :

where the methane is liberated to the environment.

The generation of oxygen led to thermodynamically favorable conditions for the oxidation of organic matter via aerobic respiration. The basic redox sequence for aerobic respiration is

This thermodynamic coupling between the photosynthetic reduction of organic carbon and the oxidation of water is reversed in mitochondria, in which oxygen is used as a sink for electrons and the oxidation of organic carbon is coupled to

Figure 3 Compilation of benthic $\delta^{18}\text{O}$ measurements from Deep Sea Drilling Program sites, spanning the past 70 Ma. The long-term increase in $\delta^{18}\text{O}$ values reflects cooling of the deep ocean and growth of ice sheets at high latitudes. $\delta^{18}\text{O} = [({}^{18}\text{O}/{}^{16}\text{O})_{\text{standard}} - 1]$, where standard is PDB. biochemical energy. Initially, the oxygen could be utilized by single-celled organisms via diffusion; subsequently, however, proteins and structures evolved that facilitated the diffusion and transport of O_2 and led to the evolution of metazoans.

Sequestration and Burial

From a biogeochemical perspective, the net evolution (i.e., accumulation) of molecular oxygen in the atmosphere means that oxidation of water and the (bio)geochemical reduction of free oxygen are not balanced, i.e., photosynthetic oxygen evolution must have exceeded oxygen consumption. Given the vast quantities of water on the surface of the planet, oxygenic photosynthesis could produce enormous quantities of oxygen without running out of substrate. When can such conditions occur and what are the oxygen-consuming reactions?

Prior to the net accumulation of oxygen in the atmosphere, oxygen produced by oxygenic photoautotrophs in the oceans would have been exposed to several potential reductants, two of which are especially biogeochemically important, namely, sulfur and iron. After Cl^- , SO_4^{2-} is the most abundant anion in the ocean. Under the mildly reducing conditions of the Archean ocean, dissolved aqueous sulfur in the ocean would have been in equilibrium between a reduced form, probably sulfide (H_2S), and the hydrated, oxidized form H_2SO_4 . The latter (sulfuric acid) would equilibrate with the alkaline or earth alkaline elements of the first and second series, resulting in the formation of ionized sulfate salts. The precipitation of sulfate minerals (e.g., gypsum) could occur in shallow seas when evaporation leads to super-saturation and during periods when the influx of Ca from continental sources is high.

The latter occurred during periods of rapid invasion of land by terrestrial plants (e.g., during the Triassic Period), where plant growth promoted weathering. Thus, photosynthetic evolution of oxygen led to the formation of vast quantities of sulfate via the oxidation of reduced sulfur anions; sulfur oxidation acted as a sink for molecular oxygen.

Under reducing conditions, iron, as Fe(II), is relatively soluble in seawater, whereas its oxidized counterpart, Fe(III), is virtually insoluble. The photosynthetic oxidation of the Archean ocean not only resulted in the oxidation of sulfur but also led to the oxidation and subsequent precipitation of iron oxides (rust) in ocean sediments. Thus, the biologically catalyzed oxidation of iron served as a second electron sink for molecular oxygen—a sink that ultimately came to represent the largest reservoir for the transition metal on Earth. The deposition of iron oxides would proceed until virtually no soluble iron remained in the ocean. The deposition of iron in Archean sediments is recorded in several deposits, the dating of which provides a record of the oxidation of the atmosphere (Figure 5).

When the electron sinks in reduced iron and sulfur were consumed, oxygen could be consumed in respiratory reactions involving (photosynthetically) reduced carbon. If, however, there was a net evasion of photosynthetically derived oxygen to the environment (i.e., the oceans and atmosphere), then a stoichiometric amount of organic carbon must have avoided oxidation, i.e., organic carbon must have accumulated. The primary sink for organic carbon is marine sediment in which, in the absence of oxygen, carbon adsorbs to inorganic sedimentary particles and becomes buried in the sedimentation process. The sequestration and burial process occurred over

Figure 5 A reconstruction of variations in the partial pressures of CO_2 and O_2 in the atmosphere through geological time using data from Berner (1990, 1993) and Berner and Canfield (1989) for the post-Cambrian epochs (i.e., the Phanerozoic). The absolute values and timing for the evolution of oxygen are not constrained in the Proterozoic Epoch.

hundreds of millions, if not billions, of years, and it resulted in the accumulation of massive amounts of organic carbon associated with sedimentary and lightly metamorphosed rocks (e.g., shales and cherts). A very small fraction of the buried organic carbon underwent alterations due to heat and pressure (i.e., diagenesis) to become fossilized carbon that literally fuels the industrialized world in the current geological epoch (Table 2).

Primary Production in the Contemporary World

The carbon remaining in photosynthetic organisms following their own respiratory costs is potentially available for consumption by other organisms. This remaining carbon, or net primary production (NPP), provides the energy requirements of all ecosystems. The distribution of NPP between the terrestrial and marine ecosystems is given in Table 4. These data suggest that terrestrial ecosystems, containing approximately 99% of the plant biomass, account for approximately 55% of the global NPP, whereas marine ecosystems, containing approximately 1% of the plant biomass, account for 45% of the productivity. The huge discrepancy between NPP per unit biomass between these two ecosystems suggests that, on average, the lifetime of marine primary producers is less than 1 week, whereas the lifetime of terrestrial primary producers is on the order of a decade or more. On land, NPP is primarily limited by the availability of water, whereas in the oceans NPP is primarily limited by the availability of essential nutrients, especially fixed forms of nitrogen.

During the past several hundred thousand years, global NPP has remained relatively constant, whereas the distribution of NPP between terrestrial and marine ecosystems has waxed and waned with climatic shifts. Briefly, every 100,000

years or so, changes in Earth's orbital relation to the sun lead to a small reduction in surface temperature, which is amplified (through unknown processes) to produce glacial periods. The advance of ice sheets in the Northern Hemisphere, combined with a reduction in liquid precipitation at low latitudes, leads to the loss of terrestrial NPP by approximately 30%. Simultaneously, however, enhanced up-welling fluxes of nutrients in the oceans combined with a strengthened eolian flux of iron stimulate oceanic NPP, such that the change between the terrestrial loss and oceanic gain is approximately balanced. During interglacial periods, the situation reverses, with a retreat of the ice sheets and the relaxation of nutrient enrichment of the upper ocean to lead to the situation shown in Table 4 for the contemporary world.

Oceanic Solubility and Biological "Pumps"

The oceans contain approximately 50-fold more organic carbon than the atmosphere, and on timescales of centuries the former reservoir controls the concentration of CO_2 in the latter. The vertical gradient of inorganic carbon in the oceans is "inverted"—that is, there is a higher concentration of inorganic carbon in the ocean interior than at the surface (Figure 6). Because the ocean surface tends to equilibrate with the atmosphere, the vertical gradient is maintained by processes other than simple equilibrium diffusion. There are two major processes responsible for the observed gradient. First, cooling of waters at high latitudes increases the solubility of CO_2 while simultaneously increasing the density of the waters. The cold, CO_2 -rich waters sink into the ocean interior, where they are transported by density discontinuities and the motion of the earth throughout the world oceans. The round-trip takes approximately 1000 years before the waters are again in

Table 4 Annual and seasonal NPP of the major units of the biosphere, from CASA-VGPM^a

	Ocean NPP	Land NPP
Seasonal		
April to June	10.9	15.7

Figure 6 Total dissolved inorganic carbon (DIC) concentration in the ocean. (A) Modeled values prior to 1765; (B) modeled values from 1990; (C) observed totals in 1990. The difference between curves C and B represents the contribution of the biological pump to the sequestration of DIC in the ocean interior.

contact with the atmosphere in the high latitude from whence they originated the journey. This “solubility” pump is responsible for approximately 50% of the inorganic carbon gradient. The other 50% is a consequence of biological activity. In the upper, lighted portion of the ocean, photosynthetic fixation of inorganic carbon by phytoplankton leads to the formation of organic matter, largely in the form of particulate materials. Gravity, acting on the particles, leads to a persistent

“rain” of organic matter into the ocean interior. The organic matter is oxidized by heterotrophic bacteria and other organisms, leading to the production of inorganic carbon. Thus, this vertical flux of organic carbon and its subsequent oxidation effectively pumps up the ocean interior with inorganic carbon. The biological pump is maintained by the upward flux of inorganic nutrients from the ocean interior, especially fixed nitrogen and phosphate. Such nutrients are essential to supporting the photosynthetic activity of phytoplankton in the upper ocean.

The Nitrogen Cycle

All organisms contain nitrogen that is reduced to the equivalent of NH₃ (ammonia). The most abundant form of nitrogen in the environment is N₂, which at the temperature and pressure on Earth’s surface is a gas and forms 78% by volume of the planet’s atmosphere. Conversion of N₂ to NH₃ requires the addition of three protons and three electrons per atom of N; the balanced equation is

This reaction is kinetically limited at low pressure and the physiological temperatures, and without some catalytic enhancement there would be no ammonia in the environment. A small subset of bacteria evolved with the capability to “fix” N₂. Nitrogen fixation, or diazotrophy (“eating nitrogen”), is catalyzed by a protein complex (nitrogenase) which is irreversibly inactivated by oxygen. The enzyme complex normally contains an Fe subunit and a Mo, Fe subunit; however, V and Fe can substitute for Mo as mediators of electron transfer in some organisms. Gene sequence analysis suggests that nitrogenase evolved from a single common ancestor, and the enzyme is primarily found in eubacteria, although some

Archea, such as methanogens, can also fix nitrogen. *In vivo* nitrogen fixation consumes approximately 16 ATP molecules per mole of N_2 fixed; this high-energy demand requires significant energy supply. In eubacteria, the supply of energy is either light (for N_2 fixing cyanobacteria), or reduced carbon substrates (for heterotrophic bacteria). For methanogens it is H_2 . Whatever the energy source, N_2 fixation is a metabolically expensive process, and hence, in the presence of high concentrations of fixed nitrogen, it usually is repressed. Many nitrogen-fixing bacteria live symbiotically with a host organism. One classical symbiosis is found in the Legumacea, which are higher plants such as peas and clover in which nitrogen-fixing bacteria are found in nodules attached to the plant root. In a second symbiosis, some insects, such as termites, contain nitrogen-fixing bacteria within their guts to supply essential amino acids to the host.

In most oxidized environments, fixed inorganic nitrogen is found in the form of nitrate (NO_3^-) or, to a lesser extent, nitrite (NO_2^-). These two oxidized forms of nitrogen are formed from ammonium via the action of nitrifying bacteria. Nitrification is a metabolic process in which the oxidation of ammonium can be coupled to the reduction of inorganic carbon to form organic molecules without light energy. This type of metabolic process is called chemoautotrophy. For example,

The pathway for ammonium oxidation is broken down between organisms that can oxidize the substrate to nitrite and those that further oxidize nitrite to nitrate. Nitrification is a metabolically inefficient process; one mole of NH_3 is oxidized to produce each mole of organic carbon. Hence, the growth rate of nitrifying bacteria is generally low, whereas in the presence of O_2 the rate of ammonium oxidation is generally rapid. Nitrification is confined to a small number of eubacteria; the gene sequence analysis of these organisms suggests the pathways evolved from single ancestral genes and are relatively conserved. Nitrate (NO_3^-) is a thermodynamically stable molecule under the oxidizing conditions of the contemporary world, and as such it is the most prevalent form of fixed nitrogen in the world oceans.

The cycle of nitrogen is completed when oxidized species of nitrogen, especially NO_3^- , are subsequently reduced to form N_2O and N_2 . This anaerobic process, called denitrification, is mediated by a wide range of diverse bacteria and Archea. Denitrification is a respiratory pathway in which the terminal electron acceptor is NO_3^- or NO_2^- . Organisms generally reduce these two substrates "opportunistically," that is, when they are deprived of oxygen. The reduction of nitrate to nitrous oxide and N_2 represents a large loss of fixed nitrogen in the environment and largely occurs in anaerobic sediments of marine and lacustrine environments and in areas of soil rich in organic carbon that are periodically flooded (e.g., rice paddies and river deltas).

Although approximately half of all the nitrogen fixed on Earth is due to natural biological activity in the environment, half is due to deliberate fixation by human activities (Figure 7). Developed in the latter part of the nineteenth century by a German chemist, the Haber reaction permits the formation of ammonium from N_2 by a high-temperature,

high-pressure reduction in the presence of H_2 . This reaction is the primary source of fertilizer nitrogen for commercial crops, without which agricultural production would be much smaller than it is currently. However, approximately 25% of the applied nitrogen to agricultural crops is lost through denitrification, leading to an increase in N_2O in the atmosphere. A significant fraction of the applied nitrogen in terrestrial ecosystems is further solubilized in waters, flowing either into groundwater or through surface waters to the sea. Most of this fixed nitrogen seldom makes its way to the open oceans; rather, due to the high rates of denitrification on continental margins (especially in sediments on the margins), the fixed nitrogen tends to be lost to the atmosphere through denitrification.

Profiles of Elements in The Sea

In the oceans there are three basic profiles to describe the distribution of elements. If an element is conservative, and is either extraordinarily abundant or does not interact with particulate matter (i.e., biological material), it will be homogeneously distributed. The soluble salts in seawater represent a vast quantity of alkaline metals, halides, and sulfates. These elements are so abundant relative to biological demands and biomass that they behave as conservative tracers; that is, their distributions are effectively uniform through the oceans. If an element is biologically reactive and can be absorbed in surface waters and subsequently transported by sinking to the ocean interior, the interior ocean can be enriched in the element relative to the surface. Such elements are said to have "nutrient-like" behavior. Examples of such elements include C, P, fixed N, Si, Fe, Cu, Ni, Cd, Hg, and the rare earth elements (REE's). It is important to note that simply because an element has a nutrient-like behavior it is not necessarily a true nutrient and vice versa. A REE, such as La^{3+} , is highly reactive with sulfhydryl ($-SH$) groups found in most proteins and hence can be "scavenged" from the surface ocean by particles. In contrast, sulfate is so abundant in the ocean that even though it is used as a nutrient in formation of proteins, the level of utilization is so small in comparison with its concentration that it behaves more like a conservative tracer than a nutrient. The third category of elemental distributions leads to an elevation in surface water and is primarily associated with an upper ocean source. One example is the vertical profile of O_2 , which is generated by photosynthetic activity in the upper ocean and consumed in the sea interior by respiration.

Sulfur

Sulfur is an integral element in two amino acids, methionine and cysteine, and hence is an essential element for protein synthesis in all organisms. The biogeochemical cycle of sulfur is primarily dependent on microbial metabolism. Under anaerobic conditions, sulfate is used as an electron sink for a wide variety of anaerobic heterotrophic microbes, leading to the formation of H_2S . This same gaseous product can be photochemically oxidized by anaerobic photosynthetic bacteria to produce reductants for inorganic carbon. Thus, a simple cycle of sulfur can be generated under totally anaerobic

Figure 7 Global N-fixation rates and emission to the atmosphere (Tg N year^{-1}) from (A) preindustrial and (B) anthropogenic sources. The boxes with dashed lines represent processes that convert unreactive N to reactive N. Reproduced from Gallaway, *et al.* (1995) N-fixation, anthropogenic influence. *Global Biogeochem. Cycles* 9: 235–252.

conditions, as long as an external energy source (e.g., light) is available to keep the system far from thermodynamic equilibrium. H_2S is also produced from geochemical reduction of sulfur in the earth's mantle and is emitted to the atmosphere and oceans through vulcanism and geothermal springs (e.g., hyperthermal deep-sea vents). The reduced sulfur flux at deep-sea vents provides a reductant for carbon fixation in symbiotic non-photosynthetic (i.e., chemoautotrophic) bacteria found in the guts of a variety of invertebrates that colonize vent regions. This metabolic pathway is also sustained by photosynthesis, albeit indirectly. The thermodynamic gradient that allows chemoautotrophic sulfur-oxidizing bacteria to extract reducing power from H_2S depends on the oxidation of the

ocean by oxygenic photoautotrophs. Under aerobic conditions, sulfur is primarily found in an oxidized form, usually as a sulfate salt, that is assimilated and reduced by photoautotrophs and microbes to a sulfhydryl ($-\text{SH}$). Hence, sulfur is both a source and a sink for metabolic electrons.

In the oceans, sulfate is the second most abundant anion following chloride. The biological assimilation and reduction of sulfur by marine microbes and plankton leads to the formation of volatile sulfur gases, notably dimethylsulfide and, in anaerobic aquatic systems, H_2S . Upon exposure to oxygen in the atmosphere, these reduced forms of sulfur are oxidized and hydrolyzed to form sulfate salts that are transported as aerosol particles. Additional sources of aerosol sulfate include

volcanic eruptions and the combustion by-products of fossil fuels, especially coal. Aerosol sulfate plays two important roles in climate feedbacks. First, the particles are hygroscopic, and upon absorption of water vapor they enhance the scattering of shortwave solar radiation (i.e., the planetary albedo). This light-scattering process tends to reduce the heating of the earth by the sun (the so-called “white house effect”). Second, as hygroscopic particles, aerosol sulfate particles provide a nucleation site for water precipitation in clouds, i.e., the particles act as cloud condensation nuclei. The atmospheric lifetime of sulfate particles is short, on the order of weeks. As water vapor builds in clouds, or the clouds are advected aloft and cool, precipitation of liquid water (i.e., rain) washes sulfate from the atmosphere. When aerosol sulfate loading is excessive (e.g., when fossil fuel combustion is high), a small fraction of hydrated sulfate in rain is not buffered by cations, and the sulfate reacts with water to form a dilute solution of sulfuric acid (H_2SO_4), producing acidic rain. Note that the transport of sulfur from continental and aquatic sources to and from the atmosphere is a consequence of phase state transitions, redox reactions, and hydrolysis.

Phosphorus Cycle

Phosphorus is an essential component of all cells; the element forms the backbone of nucleic acids, without which cells cannot reproduce. Phosphorus is also incorporated in nucleotides, sugars, proteins, and lipids. In vertebrates, almost all the phosphorus is combined with calcium to form hydroxylapatite, which is the central molecule to build bones.

In the environment, phosphorus is found almost invariably in the oxidized form as hydrated phosphate. Mineral phosphate salts erode and weather from continental sources and are carried to aquatic ecosystems as soluble ions. There is no eolian phosphorus source and no significant transfer of phosphate from aquatic or terrestrial environments to the atmosphere. Unlike carbon, nitrogen, phosphate, or oxygen, phosphorus does not undergo significant biologically mediated redox reactions; the chemistry of phosphorus is solely based on hydrolysis.

Trace Metals

Transition metals play a key role in biological electron transfer (redox) reactions and biological processes in turn affect the availability of metals in the environment. The metals are incorporated into protein “scaffolds” in specific orientations and associated with specific ligands such that the electron transfer reactions are highly specified and optimized. The transfer of electrons to given substrates is often keyed to specific metals. For example, electron transfers involving O_2 frequently are mediated by Mn, whereas electron transfers involving N frequently are mediated by Mo. The availability of transition metals, in turn, is dictated by solubility and redox conditions. Under anaerobic conditions, Mn and Mo are often sequestered as sulfide precipitates, but they become more available under oxidizing conditions. In contrast, Fe, which is a required electron transition metal in all organisms, is abundant under reducing conditions but scarce under oxidizing conditions.

As previously noted, electron transfers through iron are essential to both anaerobic and oxygenic photosynthesis, heterotrophic respiration, and nitrogen fixation. In some cases, anaerobic bacteria can oxidize Fe(II) to Fe(III), thereby precipitating iron as a ferric hydroxide in the sediment. Although iron is the most abundant transition metal in the earth’s crust, its concentration in the open ocean is extremely low, averaging no more than ~ 1 nM. To satisfy iron fluxes, eolian sources of iron are critical. Wind-blown dust from major desert areas supplies much of the iron to the open oceans. Consequently, open ocean areas, far removed from continental dust regions, have extremely low iron concentrations that result in a direct limitation of photosynthetic electron transport. Three such areas are the Southern Ocean, the eastern Equatorial Pacific, and the sub-Arctic Pacific. Ice core records suggest that during glacial periods eolian iron fluxes were much greater. The variations in dust supply appear to correspond with changes in the hydrological cycle; warm, wet climate regimes tend to reduce the eolian supply and hence may limit the biological sequestration of carbon in the oceans, whereas cold, dry periods may stimulate oceanic primary production.

Mn is essential for oxygen evolution and, like iron, its concentration is extremely low in the oceans. The Mn requirements for biological activity are lower than those for Fe; consequently, there is no evidence of Mn limitation in either the oceans or the terrestrial ecosystems. Interestingly, Mn and Fe can exchange electrons spontaneously and, in the presence of a redox gradient established in sediments, can cycle between oxidized and reduced states. Mn has two main oxidation states, namely, Mn(II) and Mn(IV). Organic carbon and NH_4 can be oxidized by Mn(IV), forming CO_2 and N_2 , respectively, whereas reduced Mn can be oxidized by O_2 and possibly by NO_3 .

Many other transition metals have been co-opted for various biologically mediated electron transfers. Mo is often utilized biologically in electron transfer reactions involving nitrogen. Most nitrogenases contain Mo, as do all nitrate reductases. Copper is frequently found in hydrophylic proteins that either catalyze single electron transfer reactions (e.g., plastocyanin) or coordinate oxygen binding (in the case of hemocyanin). The availability of these metals is inverse to those of Mn and Fe, namely, under oxidizing conditions, Mo and Cu are more abundant than under reducing conditions (Williams and Frausto da Silva, 1996).

Evolution of Biogeochemical Cycles

By definition, biogeochemical cycles are mediated in part by living organisms. The origins of biogeochemical cycles are presumably entwined with the origins of life. Although there is no consensus on the definition of life, to sustain life all living organisms must grow and reproduce. Growth is dependent on the availability of substrates and energy. C, N, P, H, O, and S are required substrates; often these substrates are combined (e.g., all organisms require phosphorus in the form of the phosphate anion, $\text{H}_2\text{PO}_4^{2-}$). All life forms either oxidize or reduce carbon; hence, carbon is either an electron sink or a source, depending on the thermodynamic basis of the

organism's metabolism. Given an external energy source, the redox reactions can run "uphill," where an environmental redox gradient is used to thermodynamically provide the free energy for the subsequent carbon reduction. This metabolic strategy characterizes chemoautotrophs. In photoautotrophs, the energy is externally provided by light. All carbon-oxidizing organisms require an alternative electron sink, such as O_2 , NO_3^- , and SO_4^{2-} .

All the basic biogeochemical cycles evolved more than 2 billion years ago in unicellular organisms. The evolution of the cycles is interdependent; that is, the requirement by all organisms to obtain reduced carbon for energy and growth created a selection pressure. Under moderately reducing conditions of the early earth, processes that led to N_2 fixation and methane production were more favorable than under oxidizing conditions; hence, these biogeochemical processes are among the earliest. Phylogenetic trees, constructed from 16S RNA sequence homology, suggest that the earliest organisms were nonphotosynthetic, thermophilic chemoautotrophs that are placed at the root branch between the Archaea and Eubacterial kingdoms. These early organisms could have used inorganic substrates, such as H_2 , H_2S , and Fe^{2+} , to reduce CO_2 to carbohydrate. Indeed, such organisms persist and thrive in deep-sea vents, in volcanic hot springs deep in Earth's crust, and in other "extreme" environments in which liquid water and suitable oxidizable inorganic substrates are available. Chemoautotrophs are almost certainly the precursors of photosynthetic cells. The evolution of a photosynthetic process in a chemoautotroph forces consideration of both the selective forces responsible and the mechanism of evolution.

Reductants for chemoautotrophs are generally deep in the earth's crust. Vent fluids are produced in magma chambers connected to the athenosphere. Therefore, the supply of vent fluids is virtually unlimited. In the contemporary ocean, the chemical disequilibria between vent fluids and bulk seawater (which is highly oxidized) provides a sufficient thermodynamic gradient to continuously support chemoautotrophic metabolism. However, the redox gradient in early Earth's oceans did not exist prior to oxygenic photosynthesis. Moreover, magma chambers, vulcanism, and vent fluid fluxes are tied to tectonic subduction regions, which are transient features of Earth's crust and hence only temporary habitats for chemoautotrophs. To colonize new vent regions, the chemoautotrophs would need to have been dispersed throughout the oceans by physical mixing. This same dispersion process would have helped ancestral chemoautotrophs exploit solar energy near the ocean surface. The evolution of photosynthetic organisms led to a highly redundant process; that is, many organisms are capable of reducing inorganic carbon to form organic materials utilizing solar energy. The ecological (i.e., "functional") redundancy ensures a continuity of photosynthetic carbon fixation in all environments in which light and liquid water are available. Currently, there are

approximately 20,000 species of aquatic oxygenic photosynthetic organisms belonging to 10 divisions; there are approximately 250,000 species of terrestrial (vascular) plants belonging to 3 divisions (Falkowski and Raven, 1997).

The evolution of oxygenic photosynthesis provided a niche for the co-evolution of ammonium and sulfide-oxidizing bacteria. The action of these organisms led to the chemoautotrophic production of NO_3^- and SO_4^{2-} , which are the most common forms of N and S found in the oceans and most terrestrial ecosystems today. The cycles of these elements are completed under anaerobic conditions, in which the oxidized forms of the elements are used as electron sinks in respiratory pathways. Under many conditions, fixed nitrogen limits primary production in both terrestrial and aquatic ecosystems. In contrast to photosynthesis, N_2 fixation is constrained to a relatively small number of bacteria, and hence the process is "functionally singular." The lack of diversity among N_2 fixers and the subsequent low supply of fixed N to many ecosystems represents a bottleneck in biogeochemical cycles. In the oceans, N_2 fixers appear to be limited by the availability of Fe and P.

Glossary

Biogeography Study of the geographic variation of nature, including variation in any biological characteristics (e.g., body size, population density, or species richness) on a geographic scale.

Continental drift Model first proposed by Alfred Wegener that states that the continents were once united and then were displaced over the surface of the globe.

Plate tectonics Study of the origin, movement, and destruction of the plates and how these processes have been involved in the evolution of Earth's crust.

Pleistocene Geologic period from 2 million to 10,000 years before the present, which was characterized by alternating periods of glaciation events and global warming.

Species composition Types of species that constitute a given community or sample.

Species richness Number of species in a given community or sample.

Introduction

Traditionally, biogeography has been defined as the study of patterns in distributions of geographic ranges (Brown and Gibson, 1983). During the past three decades, however, this field has experienced a great surge in development and sophistication, and with this development the scope of the field has broadened to include an impressive diversity of patterns. Simply put, modern biogeographers now study nearly all aspects of the “geography of nature.” Biogeography now includes studies of variation in any biological feature (genetic, morphological, behavioral, physiological, demographic, or ecological) across geographic dimensions such as distance among sites or along gradients of area, elevation, or depth (see Brown and Lomolino, 1998).

Fundamentals of Biogeography

Despite the sometimes overwhelming complexity of the natural world, all biogeographic patterns ultimately derive from two very general features of nature. First, as we move along any dimension of the geographic template, environmental conditions tend to vary in a predictable manner. For example, more distant sites tend to be more dissimilar than adjacent sites, environments at higher elevations tend to be cooler and wetter than those at lower elevations, and larger areas tend to capture more solar energy and a greater diversity of environmental conditions than smaller areas. Second, all forms of life differ in their abilities to adapt to geographic variation in their environment. These differences, while including a great diversity of responses (e.g., physiological, behavioral, developmental, and evolutionary), ultimately influence the three fundamental processes of biogeography: *immigration*, *extinction*, and *evolution*. All the biogeographic patterns we study derive from nonrandom variation in these processes across geographic gradients and across individuals, populations, and species.

Early History of the Field

Biogeography has a long and distinguished history, and one inextricably woven into the historical development of evolutionary biology and ecology. The historical development of biogeography had its origins coincident with the Age of World Explorations by Europeans during the eighteenth and nineteenth centuries. Yet the study of geography of nature must be an ancient one. The European explorers were not the first to ask “Where did life come from, and how did it diversify and spread across the earth?” Aristotle asked these same questions, as did many others before and after him, when faced with accounts of strange forms of life from foreign lands.

The development of biogeography into a mature and respected field of science, however, required a much better understanding of variation in what we now call the geographic template and the associated variation in the natural world. It is by no minor coincidence that both evolutionary biology and biogeography developed in earnest during the Age of Exploration. Prior to this time, biologists had “discovered” and described less than 1% of plant and animal forms that we know today. Each new voyage or expedition added to the accumulated information on the earth's environments and life-forms, and would eventually provide the raw material for the disciplines of evolution and biogeography. These disciplines are interconnected by the knowledge that selective pressures vary across space, and that all life-forms and their distributions are the product of natural selection.

The early explorers and naturalists did far more than just label and catalog their specimens. They soon, perhaps irresistibly took to the task of comparing their collections across regions, elevations, and other gradients of the geographic template. At the same time, they began to develop explanations for the similarities and differences among the biotas they studied. In fact, most of the persistent themes of the field of biogeography (Table 1) were well established during the eighteenth and nineteenth centuries. To be sure, biogeography has made great strides during

Table 1 Persistent themes of biogeography

1. Comparing and classifying geographic regions based on their biotas.
2. Reconstructing the historical development of biotas, including their origin, spread, and diversification.
3. Explaining the differences in numbers as well as types of species among geographic areas.
4. Explaining geographic variation in the characteristics of individuals and populations of closely related species, including trends in morphology, behavior, and demography.

the twentieth century to become a mature and sophisticated science. It is important to acknowledge, however, that we owe a great deal to the many visionary explorers and naturalists who shared our fascination and asked the same questions about the geographic variation of nature.

Historic Explorations of the Eighteenth Century

While motivated to a large degree by the quest for money and power, the Age of European Exploration was also fueled by the call to serve God. It was widely believed that the Creator had placed on this earth a still unknown diversity of organisms—a divine zoo or garden of life. Accordingly, early European explorers believed that there was perhaps no greater way to worship God than to unlock the mysteries of creation. Yet with each new account of some distant biota came information that challenged the prevailing views of creation. Eventually, the growing body of knowledge would overturn the long accepted view that the earth, its climate, and its species were immutable, unchanging in both space and time. More immediately, however, biologists of the eighteenth century were struck by the astounding diversity of species. Such diversity presented them with two serious problems, one practical and the other conceptual. First, biologists urgently needed a systematic and generally accepted scheme for classifying the burgeoning wealth of specimens, one that would reflect the similarities and differences among the species. Second, it quickly became clear that there were just too many species to be carried by Noah's Ark. How could all the forms of life, now adapted to many distant and distinct regions across the globe, have originated and then spread from that one landing point?

Carolus Linnaeus (1707–1778), certainly one of the most prominent biologists of all time, took on both of these challenges. In fact, his system of binomial nomenclature is the system we continue to use today to classify organisms. Linnaeus also attempted to rectify the Biblical doctrine with what he and his contemporaries knew about the diversity and geography of nature. This was especially challenging because, like most of his colleagues, Linnaeus was sure that species were immutable. Given this, how could species adapted to a single site and climate (Noah's landing) have spread and become perfectly adapted to a suite of different environments (e.g., alpine tundra, coniferous forests, lowland forests, and grasslands)? Linnaeus' answer: Noah's landing had occurred along the slopes of Mount Ararat, a high mountain near the border of Turkey and Armenia. This mountain is so tall (reaching 16,853 ft above sea level) that along its slopes could be found a succession of environments and communities ranging from subtropical grasslands at the lower elevations to

forests and alpine tundra at its summit. According to Linnaeus' hypothesis, each elevational zone harbored a distinct assemblage of animals, each immutable but perfectly adapted to their local environment. When the Flood finally receded, these animals then dispersed to eventually colonize their respective environments across the globe.

One of the foremost challenges to Linnaeus' views came from his contemporary Comte de Buffon (1707–1788), who believed that not only were climates mutable, but species were as well. How else could animals disperse across what are now inhospitable habitats to occupy their present ranges in such isolated regions of the globe? Buffon's theory of the origin and spread of life stemmed largely from his studies of living and fossil mammals, especially those of the Old and New World tropics. He was the first to realize that different regions of the globe, even those with the same environmental conditions, had distinct biotas. This observation was so fundamental that it eventually became biogeography's first law: Buffon's Law.

Like Linnaeus, Buffon also concluded that there was one "landing point," one site where all animals originated. However, this site, or region, was located far to the north of Mount Ararat, somewhere in the Arctic Circle where the early animals and their descendants could gain ready access to both the Old and New Worlds. This is where these life-forms survived the Flood during some earlier period when the earth's climate was much warmer, warm enough such that tropical environments could extend far poleward. Once the floods receded, animals spread southward into the continents and began to diverge in form as they became increasingly isolated on different landmasses.

Other biologists of the eighteenth century, including Joseph Banks and Johan Reinhold Forster, both of whom served as naturalist on voyages of Captain James Cook, were quick to confirm the generality of Buffon's Law: environmentally similar but isolated regions have distinct assemblages of plants and animals. Forster also discussed the relationship between regional floras and environmental conditions and, in turn, between plant and animal associations: two cornerstones of the field now known as ecology. Forster was also one of the first scientists to report that plant diversity increases as we move toward the equator, that islands have fewer plants than the mainland, and that the diversity of insular plants increases with island size and available resources. Later in the eighteenth century, Karl Willdenow (1765–1812) and one of his students, Alexander von Humboldt (1769–1859), confirmed and further generalized both Buffon's Law and Forster's. Toward the end of the century, Augustin P. de Candolle added the important insight that, not only is the distribution of organisms influenced by geographic variation in environments, but they also compete for limiting resources such as food, light, and water.

Therefore, by the beginning of the nineteenth century, biogeographers already had their first "law," they described and tested the generality of a number of related patterns about the geography of nature, and they offered some testable theories regarding those patterns. They were actively working on at least three of the four persistent themes of biogeography (Themes 1–3 in [Table 1](#)). A number of biogeographers had abandoned the notion that species and climates were immutable. But for the field to advance and become a mature science, two additional, fundamental

insights were needed. First, it required a mechanism for the mutability and adaptation of species. As many of us realize, Candolle's observations about competition and the struggle for existence were central to the development of the theory of evolution by natural selection. These advances were to come in the latter part of the nineteenth century. Second, scientists had to recognize that the geographic template (i.e., the foundation for all of these patterns) also was mutable. That is, the size and relative positions of the continents and ocean basins have changed throughout the history of our planet.

Advances of the Nineteenth Century

Many of the most fundamental advances in biogeography, and evolutionary biology as well, have required advances in geology. Until the nineteenth century, the age of the earth was typically assumed to be just a few thousand years, way too brief to allow what we now know to be the requisite time for evolution of its plates and the species that have rafted on those plates. The collective work of nineteenth-century paleobiologists would push the age of the earth back hundreds of thousands and eventually millions of years before the present. Legendary geologists and paleobiologists such as George Lyell (1797–1875) and Adolphe Brongniart (1801–1876), through their studies of fossils, provided incontrovertible evidence for extinction and for changes in regional climate and the elevation of land. How else could they explain the existence of fossils that have no contemporary forms, of fossils from tropical species found in regions that are now temperate, and of shells and other marine fossils on present-day mountains? A theory of floating and drifting continents (now known as plate tectonics) would await discoveries of twentieth-century marine geologists, but their nineteenth-century forerunners understood that the earth was very old indeed, and it was mutable. Furthermore, if species (and many thousands of them) went extinct, then there had to be multiple periods of creation (or evolution) to compensate for those losses.

Again, these views of a mutable earth, mutable climate, and mutable species were essential for those attempting to classify biogeographic regions based on their respective assemblage of species (Theme 1), to reconstruct the origin, spread, and diversification of life (Theme 2), and to explain differences in numbers and types of species among geographic regions (Theme 3). However, well into the middle of the nineteenth century many scientists held stubbornly to the idea that not only were species immutable, but so were their distributions. Perhaps the most distinguished champion of this static view of biogeography was Louis Agassiz (1807–1873), who argued that species remain essentially unchanged at or near their sites of creation.

The static view was eventually overturned by the passionate and persuasive arguments of no one less than Charles Darwin. Not only did he propose a general theory for the diversification and adaptation of biotas (i.e., natural selection), but he was one of the world's first and foremost dispersalists and champions of dynamic biogeography. Through his observations during his circumnavigation of the globe on the *HMS Beagle* (1831–1836), his later experiments on dispersal of seeds by animals, and his general synthesis on the origin and distribution of life, Darwin convinced many of his colleagues that long-distance dispersal could account for many of the

otherwise perplexing patterns of biogeography. Once he was joined by the likes of Asa Gray and Alfred Russell Wallace, Darwin and his colleagues were able to pull off a major paradigm shift in the field—from the static view of the earth and its species to the dynamic view of biogeography.

Yet among all of these visionary scientists it is Wallace who is generally recognized as the father of zoogeography, and biogeography in general. While Darwin argued passionately regarding long-distance dispersal (even to the point of soundly criticizing his mentor, Charles Lyell), most of his energies were devoted toward developing and substantiating his theory of natural selection. On the other hand, biogeography was Wallace's life's work. Brown and Lomolino (1998) listed 17 tenets of the field that were developed by Wallace and included in his seminal monographs *The Malay Archipelago* (published in 1869 and dedicated to Darwin), *The Geographic Distribution of Animals* (1876), and *Island Life* (1880). Five of these tenets of biogeography are listed here:

1. Climate has a strong effect on the taxonomic similarity between two regions, but the relationship is not always linear.
2. The present biota of an area is strongly influenced by the last series of geological and climatic events.
3. Competition, predation, and other biotic factors play determining roles in the distribution, dispersal, and extinction of animals and plants.
4. When two large landmasses are united after a long period of separation, extinctions may occur because many organisms will encounter new competitors.
5. To analyze the biota of any particular region, one must determine the distributions of its organisms beyond that region as well as the distributions of their closest relatives.

Using the latter approach and information provided by over a century of naturalists, Wallace developed a scheme of biogeographic regions (Figure 1) that accurately reflected the similarities and differences among biotas. This same scheme, largely unchanged, is still used today.

For obvious reasons, exploration and biogeographic study of the marine realm have always lagged far behind that of terrestrial systems. Yet by the middle of the nineteenth century, biogeographers had made some significant strides in studying this new frontier. Charles Lyell discussed patterns of distribution of marine algae in his seminal work *Principles of Geology*, first published in 1830. Edward Forbes wrote the first comprehensive monograph on marine biogeography in 1856, in which he divided the marine realm into zoogeographic regions based on latitude, depth, and animal assemblages. In 1897 the great British ornithologist and biogeographer Philip Sclater, who produced a predecessor to Wallace's biogeographic scheme, also developed a scheme for the marine realm based on distributions of marine mammals. Following the lead of earlier biogeographers and also based on his own extensive field studies in southwestern North America, C. Hart Merriam (1894) developed a system of what he termed "life zones" that confirmed earlier observations that elevational changes in vegetation were equivalent to those along latitudinal gradients.

Finally, the countless specimens collected during the late eighteenth and early nineteenth centuries enabled others to begin to analyze geographic variation in characteristics of

Figure 1 Alfred Wallace's (1876) scheme of biogeographic regions, which attempts to divide the landmasses into classes reflecting affinities and differences among terrestrial biotas. The regions shown are still widely accepted today. Numbers identify subregions. (Reproduced from Wallace AR (1876) *The Geographic Distribution of Animals*. London: Macmillan.)

individuals and populations (Theme 4). C. L. Gloger reported in 1833 that, within a species, individuals from more humid habitats tend to be darker than those from drier habitats (Gloger's Rule). C. Bergmann (1847) found that in birds and mammals, populations from cooler environments tended to have larger bodies than those from warmer environments (Bergmann's Rule). Also, J. A. Allen reported in 1878 that birds and mammals inhabiting cooler environments also tend to have shorter appendages (Allens' Rule).

Biogeography in the Twentieth Century

Dynamics of the Geographic Template

Even the earliest human explorers appreciated the fact that abiotic conditions vary as one moves from one point on the globe to another. On land, precipitation, temperature, seasonality, prevailing winds, soil conditions, and a host of other important factors vary as we move along transects of latitude, longitude, or altitude. Similarly, in the aquatic realm, temperature, currents, pressure, solar radiation, and concentrations of oxygen and dissolved nutrients vary markedly within and among ecosystems. Together, the variation in all of

these environmental characteristics combine to form the geographic template, which influences all biogeographic patterns.

Although a complete understanding of all aspects of the geographic template may be a daunting and truly impossible challenge, at a regional to global scale, geographic variation in environmental conditions is quite regular and interpretable. On land, climatic conditions vary in an orderly manner with latitude, elevation, and proximity to mountain ranges or oceans (Figure 2). Major soil types (Figure 3) also vary in a similar fashion, partially because soil development is strongly influenced by local climatic conditions, especially precipitation and temperature. In the aquatic realm, although the great volume of ocean waters tends to buffer variation in temperature, surface waters still exhibit a latitudinal gradient in temperature (Figure 4). In addition, throughout most of the world's oceans light availability and water temperatures tend to decrease while pressure increases with increasing depth.

As we shall see in later sections, such regular variation in environmental characteristics translates into nonrandom variation in biogeographic patterns of organisms, with each one adapted to slightly different environmental conditions. Such adaptations are, of course, the product of a long and

Figure 1 (Continued.)

complex evolutionary history: a series of innumerable interactions between organisms and their environments. With each successive generation, the abilities of descendants to respond and adapt to local environmental conditions change. Evolutionary change, however, is part of a never-ending battle because environmental conditions include other species, which are also evolving. Just as important, the geographic template has evolved throughout earth's 4.5-billion-year history. Because species distributions and other aspects of their geographic variation are influenced by their interaction with the geographic template, a thorough understanding of its dynamics in space and time is essential if we are to understand any major biogeographic patterns.

By the opening of the twentieth century, each of the four persistent themes of biogeography was well established. Explanations for the major biogeographic patterns could now draw on insights from the rapidly growing field of evolutionary biology, as well as our knowledge of the other two fundamental biogeographic processes—immigration and extinction. In addition, biogeographers of the early twentieth century could tap a great wealth of information on geographic variation of biotas and of the environments that they inhabited. Obviously, a thorough knowledge of this underlying geographic template was essential for understanding patterns in distribution and variation among regions and isolated

ecosystems. Yet to develop a more accurate and more comprehensive understanding of the major patterns and processes of biogeography, another major scientific revolution was required.

Biogeographers and most other natural scientists knew a great deal about contemporary environments, and most of them appreciated the fact that climatic conditions had changed, sometimes dramatically, during earlier periods of earth's history. Yet until the 1960s, most biogeographers clung to the belief that earth's landforms and ocean basins remained fixed. During the twentieth century, acceptance of the theory of continental drift and plate tectonics revolutionized the field of biogeography as much as acceptance of the theory of natural selection and evolution had in the previous century.

Continental Drift and Plate Tectonics

Although imperceptible to most of us, the earth's continents have moved, colliding at times and drifting apart at others: mountain ranges have formed and eroded away, seas have expanded and contracted, and islands have appeared and disappeared. These changes must have had profound effects on local and regional climates and, in turn, on the geographic distributions and variations of all forms of life on earth. As we will see in a subsequent section, the theory of continental drift and plate tectonics is a relatively recent advance. Yet, with the

Figure 2 Major climatic regions of the world. Note that these regions occur in distinct patterns with respect to latitude and the positions of continents, oceans, and mountain ranges. (Reproduced from Strahler AN (1973) *Introduction to Physical Geography*, 3rd edn., 468 pp. New York: Wiley.)

Figure 3 World distribution of major soil types. Note the close correlation of these soil types with the climatic zones shown in Figure 2, reflecting the influence of temperature and precipitation on soil formation.

possible exception of the acceptance of the theory of natural selection, no other contribution has had more of an impact on the field of biogeography.

Plate tectonics is defined as the study of the origin, movement, and destruction of the earth's plates and how these processes have been involved in the evolution of the earth's crust. The theory of plate tectonics has achieved general acceptance among nearly all scientists and reigns as a unifying paradigm of both geology and biogeography. Yet until just three decades ago, relatively late in the development of these fields, champions of this theory were viewed as oddballs and heretics.

As with any other revolutionary theory in science, it is extremely difficult to pinpoint the origins of the theory of plate tectonics. The great geologist Charles Lyell entertained the idea during the 1830s and 1840s, but then abandoned it in favor of the accepted doctrine of the fixity of the continents and ocean basins. In their attempts to explain the affinities of biotas of now isolated continents, Lyell, Joseph Dalton Hooker, and other "extensionists" of the nineteenth century hypothesized the periodic emergence of great land bridges that then allowed biotic exchange. Darwin, Wallace, and other members of the dispersal camp soundly criticized such views: nothing vexed Darwin more than those extensionists who created land bridges "as easy as a cook does pancakes." In an uncharacteristically critical passage in one of his letters, Darwin complained to Charles Lyell of "the geological strides which many of your disciples are taking.... If you do not stop this, if there

be a lower region of punishment for geologists, I believe, my great master, you will go there."

As it turns out, neither the extensionists nor the dispersalists were correct. In most cases, the similarities among now isolated biotas were instead the result of "dispersal" of the continents themselves. Perhaps the first important evidence for what was at first referred to as the theory of continental drift was the configuration of the continents. That is, once geographers had developed relatively accurate maps, it became clear to some that opposite coastlines seemed to fit. In 1858 one of Lyell's contemporaries, Antonio Snider-Pelligrini, may have been the first to demonstrate the geometric fit of the coastlines of continents on opposite sides of the Atlantic Ocean. Yet it wasn't until 1908 and 1910 that an American geologist, F. B. Taylor, and a German meteorologist, Alfred L. Wegener, independently developed models describing the movements of the earth's crust, along with the formation of mountain chains, island arcs, and related geologic features. Wegener continued to develop his model into a more comprehensive theory of continental drift, publishing his treatise in the 1920s. Wegener's theory, however, included too many assumptions about geologic processes and patterns that would not be well established for another three or four decades. His theory also included factual errors, such as overestimating the rate of movement of the earth's plates by perhaps two orders of magnitude. Finally, although he speculated on a potential mechanism, Wegener's theory really lacked a plausible one that could somehow drive the massive plates about the earth

like bits of ice on a pond in spring. It is perhaps one of history's most tragic ironies that, in his quest to discover this mechanism by exploring a volcanically active region of Greenland, Wegener perished in a snow storm.

Wegener's insights would not be widely appreciated for another three decades. Acceptance of the theory of continental drift and its maturation to become the more comprehensive theory of plate tectonics would require many additional insights from geographers, paleontologists, and especially marine geologists during the 1940s and 1950s. These scientists found that when they "rejoined" the continents based on their geometric fit, not only did their biotas seem to match up, but so did topographic features such as mountain chains, rock strata, and fossil and glacial deposits. Perhaps most critical to the acceptance of the theory of continental drift were the efforts by marine geologists following World War II to map the surface of the ocean basins. It soon became clear that beneath each ocean lay a system of ridges that were situated far offshore. As one moved away from these ridges, the seafloor became deeper and more ancient as well. Provided with these and related clues, Herman Hess and his colleagues developed the theory of seafloor spreading: continental drift finally had an underlying mechanism (Figure 5). Eventually, paleomagnetic evidence would allow marine geologists to estimate the previous positions of the continents and develop reconstructions of the sequences of their movements and creation and the dissolution of previous continents. Biogeographers were now armed with not just the evidence, but also the mechanisms responsible for the dynamics of biotas and the geographic template itself (i.e., immigration, extinction, evolution, and plate tectonics).

Glacial Cycles of the Pleistocene

The great shifting, collision, and separation of earth's plates profoundly affected the distribution of its biota, both directly and indirectly. Not only did plate tectonics alter major dispersal routes among biotas, but it substantially changed both global and regional climates. As plates shifted across different latitudes, their local biota was exposed to major shifts in climatic conditions. Areas of what is now tropical Africa, South America, and Australia once were situated over the south pole and exposed to severe antarctic climates.

On a global scale, drifting continents also triggered great shifts from periods of global warming to those dominated by glacial conditions. Land absorbs substantially more solar energy than does water. Thus, global climates tended to be warmer when landmasses were situated near the equator, but cooled as they shifted poleward.

Yet global climates can change substantially even during periods too short for substantial shifting of earth's plates. For example, during the Pleistocene (roughly the past 2 million years), earth experienced many climatic upheavals. Rather than being caused by any shifts in plates (which must have been minor given the relatively short period), these climatic shifts were caused by periodic changes in characteristics of the earth's orbit (referred to as Milankovitch cycles; Figure 6). These changes significantly altered the total amount of solar energy intercepted by the earth, ultimately causing the climatic reversals of the Pleistocene. During full glacial periods, global temperatures dropped by as much as 6 °C and most

landmasses beyond 45° latitude were covered with glaciers often 2 to 3 km thick. Because so much water was tied up in the glaciers, sea levels dropped by 100 to 200 m, thus uniting long-isolated biotas via temporary land bridges. For example, during the last glacial maximum, the region of Southeast Asia and Malaysia was united with Sumatra, Java, and Borneo to form Greater Sunda, while Australia and New Guinea formed the island continent of Sahul (Figure 7).

Winds, ocean currents, and precipitation patterns also changed substantially between interglacial and glacial periods. With each climatic upheaval, environmental regimes shifted across both latitudes and elevations. Regions such as the American Southwest, which is now dominated by desert and xeric grasslands, were once covered with coniferous forests. Warming and drying conditions that led to the current interglacial period dramatically reduced these forests and caused them to shift toward the mountain peaks, where cool and relatively humid conditions prevail.

These and other events must have profoundly influenced the distributions of most if not all biotas. As Brown and Lomolino (1998) summarize, however, all the complex biogeographic dynamics of the Pleistocene were triggered by three fundamental changes in the geographic template:

1. Changes in the location, extent, and configuration of principal habitats.
2. Changes in the nature of environmental regimes (combinations of temperature, seasonality, precipitation, and soil conditions).
3. The creation and dissolution of barriers associated with changes in sea level or elevational shifts in habitats.

The responses of both terrestrial and aquatic biotas, while no doubt complex, also were of three types:

1. Some species shifted geographically with their optimal habitats.
2. Some species remained and adapted to the altered local environment.
3. Other species, unable to modify their ranges or ecological associations, suffered range contraction and eventual extinction.

The biogeographic dynamics of the Pleistocene remains one of the field's most active and interesting study areas. Recent advances in analyzing and dating fossil material continue to add to our ability to reconstruct the historical development of biotas (Theme 2) and, in turn, understand major episodes of biotic interchange and recent extinctions, as well as the current distributions of species.

Current Trends in Biogeography

Gradients in Species Diversity and Composition

In addition to biogeographic reconstructions, modern biogeographers continue to study an impressive diversity of patterns encompassing each of the four persistent themes of the field. During the middle of the twentieth century, many biogeographers focused on more general questions. Rather than dissecting and reconstructing the range of selected species,

Figure 5 (A) During seafloor spreading, reversals in the earth's magnetic field are recorded as the magnetically sensitive, iron-rich crust cools. Differences in the widths of the magnetic stripes reveal differences in the duration of these polarity episodes and in the rate of seafloor spreading over time and among regions. (B) The current model of plate tectonics includes the possibility that at least three forces may be responsible for crustal movements: (1) ridge push, or the force generated by molten rock rising from the earth's core through the mantle at the midoceanic ridges; (2) mantle drag, the tendency of the crust to ride the mantle much like boxes on a conveyor belt; and (3) slab pull, the force generated as subducting crust tends to pull trailing crust after it along the surface. (Reproduced from Stanley SM (1987) *Extinction*. New York: Scientific American Books Inc. with permission from Nature.)

they examined trends in the total number of species, or what is often termed species richness.

Though many patterns in richness have been studied, two have received the lion's share of attention: the species–area and species–latitude relationships. Early explorers and naturalists of the seventeenth and eighteenth centuries noted the tendencies for species richness to increase with area of a region or island, and be higher for tropical versus temperate, subarctic, and arctic biotas. Armed with data from many hundreds of additional surveys and with a battery of sophisticated statistical tools, twentieth-century biogeographers confirmed the great generality of these patterns and developed some relatively simple models to explain those patterns. Often these models were equilibrational, assuming that species richness resulted from the combined but opposing effects of processes such as

immigration into an area (which added species) and extinction (which decreased species richness). MacArthur and Wilson's equilibrium theory of island biogeography is perhaps the prototypic example of such a theory, and one that has dominated the field since its first articulation in the 1960s. Their theory was developed to explain both the species–area relationship and the species–isolation relationship (i.e., the tendency for species richness to decrease as one moves from near to more isolated islands). Simply stated, because immigration rates (the number of species new to an island) should decrease while extinction rate (loss of species already present) should increase as the island accumulates species, the island should eventually reach a level of richness at which immigrations balance extinctions. This equilibrational level of richness should vary among islands: decreasing with isolation because

Figure 6 Milankovitch cycles are periodic changes in the eccentricity, obliquity, and precession of the earth's orbit. Each of these changes influences the earth's interception of solar radiation; therefore, these cycles may have been largely responsible for the glacial cycles of the Pleistocene. (Reproduced from Gates DM (1993) *Climate Change and Its Biological Consequences*. Sunderland, Massachusetts: Sinauer Association, with permission from Sinauer Associates.)

immigration rates are lower for more isolated islands, and increasing with island area because populations on larger islands should be less prone to extinction.

Biogeography in the Twenty-first Century

The equilibrium theory stimulated many studies in biogeography and related fields of ecology, and has served as the

paradigm of island biogeography for some four decades. Yet an increasing number of biogeographers are beginning to question its utility as a modern paradigm. Species richness is often influenced by speciation and disturbances (e.g., major storms and tectonic events), processes not included in MacArthur and Wilson's original theory. Either the theory has to be expanded to include these processes, or it will be

Figure 7 The lowering of sea levels during glacial maxima of the Pleistocene caused the exposure of continental shelves and the formation of dispersal routes across four regions of the eastern Pacific: Sunda, Wallacea, Sahul, and Oceania. (White areas = land exposed during glacial maxima; dark shading = deep water (>200 m); possible dispersal routes are indicated by arrows). Drawn by Simon SS. Driver from *The Journey from Eden* by Brian M. Fagan, Thames & Hudson Ltd., London.

replaced by an alternative model—one that may eventually become the new paradigm of the field.

Whatever form such a model takes, it must be sophisticated enough to address the growing complexity of questions and patterns that we now study. MacArthur and Wilson's model was primarily developed to explain patterns in richness along gradients of area and isolation. Yet modern biogeographers are now searching for a theory to explain patterns across other geographic gradients and, perhaps more important, to explain geographic trends in the types rather than just the numbers of species. Why do the proportions of large versus small, endothermic versus ectothermic, herbivorous versus carnivorous animals, woody versus herbaceous, or annual versus perennial plant species vary across geographic gradients? How are biogeographic reconstructions related to phylogenies? In what manner do gene frequencies vary with isolation or across other geographic gradients? How do the size and shape of geographic ranges vary with latitude and among taxonomic

groups, and how do population density and other demographic parameters vary across the range of a species?

We may have reached a point at which our questions and appreciation for the complexity of nature have become too sophisticated for the relatively simple models that have dominated the field since the 1960s. If this is true, biogeography may be on the verge of a major scientific revolution, one that may well rival those triggered by the seminal insights of scientists such as Charles Darwin, Alfred Russell Wallace, Alfred Wegener, Robert H. MacArthur, and E. O. Wilson.

Biogeography and the Conservation of Biodiversity

Biogeographers study both the patterns and processes influencing the geographic variation of nature. We study not just how many species occur in a particular area, but why more are there than somewhere else and which ones are likely to be

shared among areas. We study and attempt to develop explanations for what are now termed “hotspots,” regions of relatively high numbers and high endemism of species. Biogeographers also study variation in the geographic template, including that associated with anthropogenic disturbances such as the spread of exotic species or the spatial patterns of deforestation. Many biogeographers study extinction and have demonstrated that it has a geographic signature: loss of species tends to be highest for the smallest and most isolated sites, namely, oceanic islands and fragments of once expansive habitats on the mainland. Given this, it becomes obvious that few disciplines could be any more relevant to understanding and preserving biological diversity than biogeography.

Our task, however, is far from a simple exercise of just applying what we already know. Indeed, only a small fraction (perhaps just 2 or 3%) of all extant species have been described, and we know precious little about the geographic distributions of most of those. What we do know often comes down to just general patterns for common species, but conservation biologists require detailed information on the rare species—those that may be the exceptions to most rules.

We have, however, made great progress in recent years in mapping and measuring the intensity (number of endemic species) of hotspots of biological diversity. In theory, these hotspots of biodiversity should receive the highest priority from conservation biologists, especially when they coincide with high levels of human activity. Yet even these approaches, generated by existing survey information and sophisticated geographic analyses, are based on a relatively limited number of surveys.

To develop more effective strategies for conserving global diversity, we still require a much more thorough understanding of the geographic variation of nature. A number of distinguished ecologists and biogeographers, including E. O. Wilson, have called for greatly accelerated efforts to map the diversity of life. With adequate support, within just a few decades we could greatly expand our knowledge of the distributions of most life-forms and, eventually, contribute to their conservation as well.

Dispersal Biogeography

Ran Nathan, The Hebrew University of Jerusalem, Jerusalem, Israel

© 2013 Elsevier Inc. All rights reserved.

Glossary

Dispersal The movement of disseminules away from their source, either their place of birth or their breeding site. Because of the variety of disciplines involved with the study of movements of organisms, the term is often misused and confused with a plethora of movement terms. The term dispersion refers to the fine-scale spatial distribution pattern of organisms, and migration is in some cases equivalent to dispersal, though it typically refers to a particular (directional and synchronized) type of movement. The term immigration is dispersal from the perspective of the recipient locality regardless of the source – the arrival of new individuals to an area previously not occupied by that species. It should be emphasized that dispersal *per se* does not deal with events that occur after a movement has been completed and the term “effective dispersal” should be used for events of dispersal followed by successful establishment. Similarly, the term colonization should be used for incidents of immigration that are followed by establishment of a viable population.

Dispersal barrier The species-specific physical and biological restrictions a propagule must overcome to accomplish successful colonization.

Dispersal biogeography Usually refers specifically to “a branch of historical biogeography that attempts to account for present-day distributions based on the assumption that they resulted from differences in the dispersal abilities of individual lineages” (Brown and Lomolino, 1998; p. 628). More generally, it is the study of the relationships between dispersal and the geographical distribution of organisms. The latter definition is adopted for this article.

Dispersal route The particular set of physical and biological conditions that allow organisms to cross dispersal barriers.

Disseminule The unit of dispersal; any part or stage in the life cycle of an organism that is used for dispersal.

Propagule The unit of colonization; a disseminule, or group of disseminules, which has the full potential to establish a new population.

Range expansion The spatiotemporal process in which successive colonization events increase the size of a species’ geographical range. The terms invasion, migration (as used in the botanical literature), and spatial spread are roughly synonyms for range expansion. Invasion, in particular, is often used to describe colonization far outside the natural species range.

Introduction

In Chapters XII and XIII of *The Origin of Species*, Charles Darwin (1859) discussed how patterns of geographical distribution of species are related to his ideas of natural selection. He argued that “all the grand leading facts of geographical distribution are explicable on the theory of migration, together with subsequent modification and the multiplication of new forms.” Darwin illustrated this argument through many examples, by explaining different biogeographic patterns, emphasizing the role of dispersal barriers (*see* Glossary) and the various means of long-distance dispersal (LDD) through which organisms are able to cross them. Although Carl Linnaeus (1707–1778) and Augustin-Pyramus de Candolle (1778–1841) had already expressed similar ideas about the importance of dispersal in determining species distributions, Darwin (1809–1882) and Alfred Wallace (1823–1913) are those most identified with the dispersalist school. This school asserts that disjunction and range expansion occur through rare LDD events across preexisting barriers. Joseph Hooker (1817–1911), one of Darwin’s closest confidants, viewed LDD across barriers as extremely unlikely and argued that range expansion was possible only across ancient land bridges that once connected currently disjunct continents. He thus argued that biogeographic disjunction can be explained by vicariant (splitting) events in which new barriers have

subdivided a previously continuous range. Evidence for Hooker’s land bridges never emerged; however, the two basic opponent ideas of dispersal versus vicariant history were already brought onto the front stage of biogeography. In *The Secular Ark*, Browne (1983) describes the nineteenth-century discussion on this issue involving Darwin, Wallace, Hooker, and others.

The twentieth century has seen a further polarization of the vicariance/dispersal debate. Plant biogeographers such as Evgenii Wulff (1885–1941) and Stanley Cain (1902–1995) reiterated serious doubts about the ability of LDD to account for present plant disjunctions, in light of the extreme rarity and lack of direct empirical evidence of these events. Others, like Philip Darlington (1904–1983), advocated Darwin’s dispersalist view, but without Darwin’s reliance on specific centers of origin. In particular, the equilibrium theory of island biogeography (MacArthur and Wilson, 1967) ascribes a critically important role to immigration (*see* Glossary) in determining the number of species on islands. This landmark theory, which had a major impact on both ecology and biogeography, modeled the probability of immigration of a new species as roughly a negative exponential function of the number of species on an island, with the rate also decreasing with distance from the mainland.

At approximately the same time that Robert MacArthur and Edward Wilson published their theory, the important theory

of continental drift, or, more generally, of plate tectonics, first proposed early in the twentieth century, was finally accepted. This theory provided a vicariant mechanism to explain biogeographic disjunctions without LDD events. In the 1970s and the early 1980s, the concept of vicariance biogeography received much attention among biogeographers, as reflected in three books by Nelson and Rosen (1981), Nelson and Platnick (1981), and Wiley (1981). The main argument raised against dispersalists' explanations, following the similar criticism by Leon Croizat (1894–1982), was that LDD is a unique, highly stochastic and unpredictable phenomenon; hence, its relationships with species distributions are not testable. However, truth and testability remain distinct: Obstacles to proving the truth of an idea do not imply its falsehood. The explanations of biogeographic patterns by dispersalists were condemned as "story-telling" scenarios which "in explaining everything really explain nothing." However, solutions of complex biogeographic patterns by vicariant events alone, if taken to their limits, are also speculative. There are, indeed, examples of extreme cases in which disjunctions are exclusively explained by dispersal (e.g., colonization of remote newly created islands) or by vicariance (e.g., postglacial relicts). However, none of these extreme arguments provides a general explanation. In fact, as shall be seen, not only do both phenomena exist, but they also frequently co-occur.

The dispersal–vicariance debate reflects a more general controversy over the biogeographic relevance of dispersal: To what extent does dispersal influence species distribution? This debate concerns whether disjunct distributions have resulted from dispersal across a barrier or from a barrier splitting a continuous range. But dispersal and vicariant events are not the sole explanations for disjunctions, which may also result from differential extinction within a species range. The major problem in limiting dispersal biogeography to its currently narrow definition (*see* Glossary), is that such a definition reduces the entire phenomenon of dispersal to LDD across barriers, thereby ignoring the various biogeographic patterns to focus solely on disjunct distributions. As this discussion will show, there are many other distributional patterns that cannot be explained by either vicariant or extinction events but only by long- and short-distance dispersal events. Rich evidence gathered from diverse independent sources indicates not only that LDD exists, but also that it is the only possible explanation for the geographical distributions of many species, such as the Hawaiian biota (Carlquist, 1974). Furthermore, LDD is not necessarily as random or unpredictable as it is often considered. The relative importance of dispersal varies between species, biogeographic regions, and times. Thus, to assess the relative biogeographic importance of dispersal, one needs to explore the nature of dispersal and its relationships with the geographical distribution of species. The broader view of dispersal biogeography (*see* Glossary) propounded here aims to understand how dispersal influences, and is influenced by, the geographical distribution of organisms. This view has received enormous support since the publication of the first version of this article in 2001, giving rise to a balanced approach recognizing the importance of both dispersal and vicariance (de Queiroz, 2005; Crisp *et al.*, 2011).

Perspectives on Dispersal

The Ecological Perspective

As a general rule, most disseminules (*see* Glossary) travel relatively short distances from their parent source. The basic description of dispersal, called the dispersal curve, is a graph plotting the distribution of disseminules against the distance from their parent source (Figure 1). The dispersal curves, derived for a great number of organisms, show not only tremendous variability, but also a right-skewed leptokurtic distribution with overwhelming regularity. That is, they typically describe a rapid decline in disseminule density with distance from their parent source, with more disseminules both near the source and along the tail than a corresponding normal distribution (*see* Dispersal Models). The restricted spatial extent of dispersal has important implications for the dynamics of populations, metapopulations, and communities and for other topics addressed in ecological studies of dispersal (Nathan and Muller-Landau, 2000).

The ecological perspective of dispersal is concerned not only with small spatial scales, but also with relatively short temporal scales. Dispersal is often restricted to early stages during an organism's life cycle (seeds, eggs, larvae, and juvenile stages in animals); the term natal dispersal denotes dispersal of young animals whereas breeding dispersal indicates dispersal of reproductive adults. Disseminules of many plants, nematodes, rotifers, desert butterflies, copepods, and other invertebrates can persist for years – sometimes hundreds of years – as dormant seeds or eggs, providing the means for a temporal exploration for favorable establishment conditions. From another temporal perspective, dispersal is typically a seasonal phenomenon, and synchronization of dispersal in different individuals, populations, and species is fairly common in both animal and plant communities. It is important to keep in mind that dispersal does not always lead to successful establishment and reproduction in the next generation. In fact, the seed-to-adult survival probability is rarely high in any species and in many, if not most, species can be extremely low. Cases in which dispersal has been followed by successful establishment are often called "effective dispersal" and nearly all referrals to "dispersal" in the biogeographic perspective actually mean effective dispersal. However, the importance of distinguishing the (small) subsample of effective dispersal cases from all dispersal events is now widely recognized in dispersal ecology studies (*see* Ecological Opportunity: Postdispersal Establishment); the growing use of terms like "long-distance dispersal and establishment" (Crisp *et al.*, 2011) in dispersal biogeography literature implies an emerging agenda to explore the distinct role of transport processes and postdispersal establishment.

The Evolutionary and Population Genetics Perspectives

The great variety of dispersal-determining traits presents clear evidence that dispersal is of important adaptive value for many life forms on Earth. From the evolutionary perspective, the study of dispersal is concerned with the source and significance of this variation: The factors and processes that affect the advantage of dispersal. Typically, dispersal is advantageous for escaping the high mortality near the source, reducing

Figure 1 Dispersal diagrams representing the distribution of dispersal distances, for the winged seeds of Aleppo pine (*Pinus halepensis*) (a) and for first-year woodpigeons (*Columba palumbus*) (b). Dispersal of pine seeds was estimated by combining mechanistic simulation of wind dispersal with seed-trap data collected during six dispersal seasons in an isolated pine stand on Mt. Carmel, Israel, whereas bird natal dispersal was estimated with permission from ringing and recovery data gathered in Britain from 1909 to 1994. Note the three-order of magnitude difference between abscissas. Pine data reproduced from Nathan R, Safriel UN, and Noy-Meir I (2001) Field validation and sensitivity analysis of a mechanistic model for tree seed dispersal by wind. *Ecology* 82: 374–388, and the bird diagram was redrawn from Paradis E, Baillie SR, Sutherland WJ, and Gregory RD (1998) Patterns of natal and breeding dispersal in birds. *Journal of Animal Ecology* 67: 518–536.

competition with close relatives, minimizing the fitness cost of inbreeding depression by reducing the chances of mating with close relatives (in sexual species), and for locating new resources for establishment, growth, and reproduction. Theoretical models (see Johnson and Gaines, 1990, for a review) show that even in environments in which the physical conditions are stable in time and space, surprisingly high proportions of dispersing progeny may be adaptive. Since mutations beneficial to successful dispersal are typically rare, evolutionary effects are observable only at relatively long time scales (but see The Geography of Dispersal). However, there is no characteristic spatial scale for the evolutionary perspective of dispersal. Adaptive advantages of dispersal are expressed at both small and large spatial scales.

Dispersal provides the means for gene flow within and among populations; thus, studies of population genetics explore how dispersal, in conjunction with the breeding system

and selection regime, affect the genetic structure of populations. In general, high rates of dispersal lead to mixing of genotypes and thus lower regional genetic diversity, whereas low rates of dispersal (isolation) typically result in low local genetic diversity, but high regional diversity. Although these effects may also occur at small spatial and temporal scales, they are notably more pronounced in large ones.

The Biogeographic Perspective

Dispersal becomes important at the biogeographic level at large temporal or spatial scales when and where propagules disperse outside the species range and successfully establish viable populations (see Components of Colonization Success). The identification of locations as “within” or “outside” the species range (and obviously the definition of a species range itself) is problematic since sampling of any species is typically

incomplete. Even if one assumes complete information on the exact location of each individual at any particular time, the issue of species boundaries is difficult because each species exhibits a profound variation in its local density and, in fact, is entirely absent from most locations. In biogeography, this distinction is less problematic when dealing with larger spatial and temporal scales.

Spatial spread can occur at different rates and can generate different spatiotemporal patterns, from slow gradual expansion to abrupt long-distance jumps. Both rate and pattern depend on the two basic components of spatial progression the movement itself (dispersal) and local population growth (reproduction) – and their interplay (*see* Modeling). The biogeographic literature provides numerous examples showing a continuum between these extremes, and it is also clear that gradual spread and long jumps can follow each other. However, there are basic differences between these two modes: Gradual range expansion is the outcome of multiple ordinary (i.e., short-distance) dispersal events over a relatively long time period, whereas jumps are rare individual LDD events that abruptly change the species' range.

Gradual Range Expansion

Gradual range expansion is the continuous spread of populations through multiple ordinary (short-distance) dispersal events, usually over quite long time scales. Very slow expansion has been termed secular dispersal (or secular migration); more rapid (though still gradual) expansion is referred to as diffusion (Pielou, 1979). Examples of gradual range expansion are the initial spread of mollusks, worms, crabs, and fishes from the Red Sea to the Mediterranean (*see* Removal of Barriers), and of muskrats in Europe (*see* The Spread of Alien Species).

Jump Range Expansion (Jump Dispersal)

Although most dispersal is limited to relatively short distances and therefore covered appropriately by the ecological scale (*see* The Evolutionary and Population Genetics Perspectives), rare LDD events have crucial implications for biogeography. There is enormous variation in the ability to disperse disseminules over large distances within and, more significantly, between species. Specific morphological characteristics are associated with LDD ability (Box 1). When such an event ends in establishment, the spatial spread is clearly discontinuous. The frequently used term for this type of spatial spread, jump dispersal, does not fully describe the process: Spatial spread is not only restricted to the movement phase (dispersal), but also necessitates establishment. Hence, the term jump dispersal should be replaced with jump range expansion. Note also that although the original term is appropriate for describing LDD over barriers, the term jump range expansion is also applicable to situations in which suitable habitats are as common in the gap as in the recipient area but are unoccupied (*see* Holocene Postglacial Spread and Dispersal Models).

Previous studies have suggested many methods of classifying the various means of dispersal. The most fundamental distinguishes between organisms that are actively dispersed (by their own power) and those that are passively dispersed (by a physical agent or by other organisms). Organisms unusually capable of active dispersal are said to be vagile,

whereas those unusually capable of passive dispersal are called pagile. Another common classification, mostly used for plants, is based on the primary dispersal agent, using the suffix chory (to disperse) at different levels: For example, zoochory is dispersal by animals, omithochory by birds, and endozoochory is within an animal. Neither classification should be taken as an absolute: Many vagile organisms also disperse passively, and many pagile organisms can move actively over short distances. Seeds of many plants are actually dispersed by multiple agents, rather than by a single one (Nathan *et al.*, 2008b).

Relatively few animals have the capacity to travel long distances under their own power. Most of these are volant (flying) species such as birds (Box 1(a)), bats, and butterflies, as well as large mammals, reptiles, and fishes capable of swimming across the oceans. Although many migrate seasonally, this large-scale movement usually does not affect the geographical distribution of the breeding range. However, extra-limital sightings are well documented for many taxa, and occasionally may result in the establishment of a new colony outside the species range (*see* Recent Range Expansion). Nonvolant animals cannot vault dispersal barriers as do flying animals, rendering their active dispersal generally less effective. In plants, active dispersal is very rare and is restricted to the phenomenon of ballistic dispersal, in which seeds are explosively discharged from their base (Box 1(b)) and are dispersed at most tens of meters.

Passive dispersal is the main, or sole, means of movement for the vast majority of organisms. In plants, morphological appendages such as wings or hairs aid the passive wind dispersal of diaspores (Box 1(c)); barbs or spines adhere to mobile animals; fleshy fruits attract frugivores that may digest the fruit and defecate the seeds (Box 1(d)). Seed dispersal by volant vertebrates (especially birds and bats), either external (epizoochory) or internal (endozoochory), has traditionally been considered an efficient adaptation for LDD. However, plant seeds can be transported over long distances irrespective of their dispersal morphology; therefore, generalizations about LDD should not be based on seed morphology but on attributes of potential LDD vectors (Nathan *et al.*, 2008b).

Passive dispersal is also frequent among organisms other than plants. Many marine organisms have free-living juvenile stages in the form of cell, eggs, or larvae that are carried passively by ocean currents over large distances. Being concentrated near the water surface, these tiny planktonic propagules (Box 1(e)) are dispersed by the wind-driven oceanic circulation. Microbes, spores, light seeds, and tiny insects, spiders, and mites constitute the so-called aerial plankton known to be an extremely effective source of colonization of remote islands. Some spiders, for example, climb to a high point, release silk parachutes into the air, and are subsequently carried off by wind. Dispersal of larger disseminules by winds is usually very local, but strong updrafts and extreme storms can carry them over large distances. Another passive mechanism for dispersal of relatively large organisms is by floating islands or rafts (Box 1(f)), which may disperse entire trees, rodents, and reptiles, again, irrespective of their morphological adaptations for dispersal. However, the most influential dispersal agent at the biogeographic scale – at least during the past 10,000 years – is man. Anthropogenic dispersal has moved many species of almost any dispersal adaptation across the globe (Carlquist, 1974),

either intentionally or not. The arrival of the brown tree snake to Guam is considered to be unintentional (*see* Extinction); years later, a snake was found in an airplane's wheelwell just before leaving Guam for Japan (Box 1(g)).

The probability of LDD is inherently very low, and jump range expansion also requires the unlikely discovery of a suitable site and establishment of a viable population in a remote location. Jump range expansion is thus highly improbable (*see* Components of Colonization Success). This improbability might lead one to doubt the biogeographic importance of LDD (*see* Introduction). However, even extremely low (but nonzero) probabilities will eventually be realized given enough attempts. In fact, there are large numbers of examples of jump range expansion, including, but not restricted to, the colonization of newly formed volcanic islands (*see* Colonization of Virgin Habitats).

The low probability of jump range expansion implies that this phenomenon is highly stochastic and unpredictable; although this generalization is true to a large extent, there are several predictable mechanisms of jump range expansion. Nathan *et al.* (2008b) proposed six generalizations for the key mechanisms driving LDD of plant seeds and other passively dispersed organisms, stating that LDD is generally more common in open terrestrial landscapes, and is typically driven by large and migratory animals, extreme meteorological phenomena, ocean currents, and human transportation (*see* Box 1), each transporting a variety of seed morphologies.

Determinants of Dispersal and Colonization Success

Mechanisms and Adaptations for Dispersal

Most (if not all) organisms are able to move or be transported at some stage during their life cycle, exhibiting a diverse array of dispersal mechanisms (Box 1). Henry Ridley (1930), Sherwin Carlquist (1974), and Leendert van der Pijl (1982) provide many examples of dispersal-determining traits in animals and plants. Overall, organisms vary greatly in their dispersal ability, the capacity for dispersal, which is determined by a complex set of interacting factors. High dispersal ability can be achieved by either active or passive dispersal (Box 1), and it is often associated with relatively low competitive ability and short longevity.

Components of Colonization Success

Successful colonization necessitates that the physical presence of a propagule will be followed by establishment. Both dispersal and establishment require physiological, morphological, and behavioral preadaptations or adaptations enabling them to disperse far from the source, survive during dispersal, and become established in a remote location. In general, the larger the distance between any two locations, the more dissimilar the environmental conditions. Therefore, LDD typically takes propagules to environments that are very different from their usual habitats (Nathan, 2006). Thus, successful colonization in remote locations is generally extremely rare, because it is the product of the very low probabilities of these sequential processes. However, given enough

time and multiple attempts, LDD may result in long-distance colonization.

Preadaptations

Species that often combine high dispersal ability with broad ecological tolerance are those adapted to exploit disturbed or newly created environments and those that inhabit ephemeral or uncertain environments. Such species are thus preadapted for successful colonization outside their species range. MacArthur and Wilson (1967) called these species *r*-strategists, characterized by small size, early maturity, rapid growth, high fecundity, high dispersal ability, and broad niche. In contrast, *K*-strategists are better adapted for local competition through the efficient use of limited resources. The dichotomous *r/K* scheme is obviously an oversimplification and the concept is rather controversial (*see* Williamson, 1996); yet empirical studies generally, but not always, do support the theoretical expectation that *r*-strategy preadaptations characterize effective colonizers (Brown and Lomolino, 1998; *see* Removal of Barriers).

Physical Access: Dispersal Barriers and Dispersal Routes

Physical access to a remote location depends not only on specific traits that enhance LDD (Box 1), but also on the environmental conditions in the area between the source and the deposition location. Crucial to the problem of physical access is that of dispersal barriers, which propagules must overcome during jump range expansion (*see* Jump Range Expansion (Jump Dispersal)). The manner of overcoming barriers defines the dispersal route (*see* Glossary), the other key term in the context of physical access; some routes may be traversed with ease, whereas others rely on chance. Examples of dispersal barriers and dispersal routes are given in the section Removal of Barriers and in other sections that follow.

It is important to emphasize that dispersal barriers are species-specific; that is, conditions that may prevent dispersal of one species may not affect the dispersal of another. They may even be specific for a particular stage in the species' life cycle. Dispersal barriers can be physiological, ecological, or behavioral, with organisms subjected to physiological stresses, ecological hazards, or behavioral difficulties in the environments they traverse.

Dispersal barriers become traversable via dispersal routes. George Simpson (1902–1984) made a distinction between corridors, filters, and sweepstakes routes, which roughly cover the entire range of probabilities of crossing a barrier from highly probable to highly improbable, respectively (Simpson, 1965). Corridor routes allow dispersal of many species from one region to another, conferring a considerable degree of similarity between the biotas of the two sides. Climatic changes and plate tectonics have repeatedly connected previously separated land or water masses, generating dispersal corridors such as those between Africa and Eurasia (*see* Spread of Early Hominins; Figure 2). The passage through filter routes is more selective than through corridors. Some species pass rather easily, whereas others do not. As a result, each biota represents a biased subset of the other. The Suez Canal between the Red Sea and the Mediterranean Sea (*see* Removal of Barriers) is an example of a filter route. Sweepstake routes in which crossings occur as a chance event

Figure 2 Major episodes of biotic interchange during the late Miocene, Pliocene, and Pleistocene-Recent. Roughly symmetrical interchanges are marked by two-headed arrows, asymmetrical ones by single-headed arrows pointing at the predominant direction, and uncertain direction by question marks. Reproduced from Vermeij GJ (1991) When biotas meet: understanding biotic interchange. *Science* 253: 1099–1104, with permission from American Association for the Advancement of Science.

at a very low frequency, such as by dispersal on floating islands (**Box 1**), represent the most improbable way to cross a barrier (see Colonization of Virgin Habitats).

Ecological Opportunity: Postdispersal Establishment

Given that physical access has been attained, nevertheless the probability of successful colonization in remote areas is still rather low. As indicated above (see Preadaptions), both the physical access and the establishment of a viable population require physiological and morphological preadaptations; often each characteristic is restricted to either dispersal or establishment, and plays little role in the other. The importance of postdispersal establishment for successful colonization is illustrated by the many examples in the section Methodological Approaches and Case Studies.

Establishment success is determined in part by the ecological conditions at the new site. For passively dispersed

species, the interaction between the dispersal vector and the conditions in the particular arrival site matter, whereas actively dispersed propagules may exhibit habitat choice (also called habitat preference) due to their ability to reach preferred habitats among those locally available. Passively dispersed dormant propagules like seeds and invertebrate eggs may exhibit temporal habitat choice by becoming dormant until conditions favorable for establishment become available. Meeting the physical conditions for establishment may not be sufficient since colonizers may still be excluded by biotic interactions such as competition and predation. Thus establishment also requires traits specific to the recipient community, particularly in relation to the resident competitors and predators.

Successful colonization in remote areas requires that colonists be able to reproduce and establish a viable population. Given that LDD is likely to bring only one or very few

reproductive individuals close together in a remote area, the initial population size of a naturally colonizing species is typically very low. Very small populations are prone to extinction due to demographic, genetic, and environmental stochasticity – the influence of random events on population persistence – which is intensified as population size decreases. These risks may be reduced with repeated immigration to the site, by the so-called rescue effects (*see* Extinction). Hence, dispersal ability itself is a factor that determines not only arrival but also, in part, establishment probability. Small, newly established isolated populations exhibit reproductive difficulties due to Allee effects such as difficulty in finding a mate. Such effects are obviously graver for obligate sexual reproducers (higher animals and plants) than for asexual or self-compatible organisms that can reproduce without gametes from another individual. However, the severity of Allee effects might be reduced in some obligate sexual species by certain reproductive mechanisms, such as sperm storage and delayed implantation, which assure sufficient gametes of both types, as well as by social behavior such as flocking.

The Geography of Dispersal

The main issue addressed thus far is the effect of dispersal on the geographic distribution of organisms. The complementary issue of the effects of geography on dispersal is dealt with in the discussion of dispersal barriers and dispersal routes (*see* Physical Access: Dispersal Barriers and Dispersal Routes). This topic is concerned with the geographic variation in dispersal explained by geographic variation in the external factors affecting dispersal. It typically neglects geographic effects on the dispersal traits themselves. Theoretical models predict that dispersal is favored during colonization, but selected against when a population is strongly isolated. The degree of isolation is a relevant factor: (1) when isolation is low, colonization is easily achieved by dispersal. Thus, elevated levels of isolation initially select for greater dispersal abilities; (2) at higher levels of isolation colonization is unlikely, and dispersal is selected against. Although the second prediction has long been recognized and is supported by overwhelming evidence, there have been only a few recent tests of the first.

The prediction that very high degrees of isolation select against dispersal is evident in the loss of dispersal ability on oceanic islands, as in many flightless birds, land snails, insects, and plants (*see* Carlquist, 1974). Reduced dispersal is also evident in organisms in unique isolated habitats as diverse as subterranean caves, mountaintops, deep-sea trenches, thermal vents, and hot springs. The observation of this phenomenon raises an intriguing paradox, which Darwin (1859) explained through counteracting selective forces acting before and after colonization of a remote island. Cody and Overton (1996) demonstrated the strength of the selection for reduced dispersal potential in weedy, short-lived wind-dispersed plants of inshore islands in Canada. Over the course of just a few generations, island populations of two of three species with sufficiently large sample sizes showed marked reduction in dispersal potential relative to mainland populations or young island populations. Aphids, leafhoppers, crickets, and many other insects have the potential to develop into a normal or

flightless adult, depending on the environmental conditions encountered during development.

Habitat fragmentation has substantial effects on dispersal at mesoscales by creating dispersal barriers and disrupting dispersal routes. Studies on British butterflies (Van Dyck and Matthysen, 1999) show that the relative investment in the thorax, which mainly contains flight muscles, is higher when patches are >40 km apart; similar selection appears to have occurred in a region where population expansion was most rapid. No differences were found in the relative investment in flight between sites <5 km apart. Since flight is associated with other functional needs of butterflies such as foraging and mate-location, further study is needed to test the relationship between morphological traits and dispersal ability.

Methodological Approaches and Case Studies

Observing Dispersal and Colonization in Action

Observations of Dispersal

Direct observation is potentially a powerful method of quantifying dispersal. Turchin (1998) provided an extensive review and explanation of the various methods used to track the movements of individuals and to estimate population redistribution in both animals and plants, including records of movement paths and mark-recapture methods. These methods are typically laborious and, from a biogeographic perspective, where large spatial or temporal scale are most important (*see* The Biogeographic Perspective), nearly impossible. The indirect approach, in which dispersal is estimated from its outcome (recruitment), is more feasible. The greater feasibility of indirect methods is a result of the larger size and more conspicuous nature of most mature organisms in relation to their propagules; moreover, it is usually easier to observe a pattern (recruitment) than a process (dispersal). As emphasized in the section Components of Colonization Success, dispersal is meaningless without subsequent recruitment; therefore, indirect evidence of dispersal is indeed important. Nevertheless, it does not tell us much about the dispersal process itself, since the distances dispersed, the number of dispersal events, and the mechanisms of unsuccessful recruitment are unknown. These are important parameters that should be incorporated into biogeographic models in order to enhance their generality and predictive ability.

Data on dispersal events are best obtained by following movements of individuals for which both source and end points are known. Unfortunately, for practical reasons, these kinds of data are relatively rare. In many cases, only the end location is known and there are multiple potential sources. Although our knowledge of LDD continues to increase, the paucity of direct observations of these dispersal events is one of the largest obstacles to the development of dispersal biogeography as a mature scientific discipline. One possible solution is the development of methods to track individual movements at both small and large spatial scales. Advances in developing molecular and remote sensing techniques promise significant progress in the near future and have already yielded new insights into dispersal processes. For example, using a variety of molecular tools, Vilà *et al.* (2003) showed that even

a single immigration event of an individual gray wolf (*Canis lupus*) can recover genetic diversity in a severely bottlenecked and geographically isolated population in Norway. However, the origin of this wolf has been debated, since the closest known population lies >900 km away in Finland, beyond the known dispersal distance of this species. Doubts have lessened given that a young GPS-tracked female wolf has been recorded as having traveled a total straight-line distance of >1000 km from Norway to the Finish–Russian border (Wabakken *et al.*, 2007). Note that in genetic studies, the term “direct evidence” is used for evidence of gene flow obtained by comparing the genotypes of recruits and their putative parents (and then applying methods such as paternity analysis to identify the most probable parent). That would be considered as indirect evidence under the preceding definition. However, for the study of LDD this approach is not very valuable. Identifying putative parents becomes impractical as the distance from the offspring increases. In contrast, the so-called indirect genetic approach, which compares the genetic structure between populations, has provided compelling evidence for jump range expansions (*see* Holocene Postglacial Spread).

There are two types of methods for estimating the dispersal distances when there are multiple possible sources (reviewed in Nathan and Muller-Landau, 2000). The first makes *a priori* assumptions about the source location (of which the simplest assumes the nearest possible parent is the source), whereas the second uses inverse methods to fit a particular dispersal kernel (a functional form of the probability distribution of dispersal distances – *see* Dispersal Models). Both methods have been applied to study dispersal at the ecological scale. Since short-distance dispersal governs gradual range expansion, it is also important from the biogeographic perspective. However, using these methods to estimate LDD is problematic since the exact position along the dispersal kernel tail is typically very sensitive to small differences in probability, thus sampling errors are likely to obscure the actual probabilities. Furthermore, the number of endpoints is typically very small (in most cases there is only one), which prohibits inverse modeling techniques. With a better understanding of the process of LDD itself, mechanistic dispersal models help surmount this difficulty (*see* Dispersal Models).

Colonization of Virgin Habitats

Volcanic eruptions that eliminate an entire local biota provide unique opportunities to study patterns of dispersal and colonization. Although there are some well-studied cases of recolonization in terrestrial systems after volcanic eruptions, such as the 1980 eruption of Mt. St. Helens (western North America), the best case studies are of oceanic islands. A well-known example is the island of Surtsey near Iceland that emerged from the sea in 1963. The best example, however, has its roots 80 years earlier. On 27 August 1883, the island of Krakatau, located between Sumatra and Java (Figure 3(a)), exploded with tremendous force, obliterating all traces of life. Less than 2 months after the eruption, a Dutch expedition found no evidence for any surviving life form. The first animal, a single tiny spider that had dispersed as aerial plankton (Box 1), and the first plant, were detected 9 and 13 months after the eruption, respectively. Later biological surveys documented the rapid recolonization of the island by various life

forms, in a complex successional process, which began with fungi and lichens breaking down the volcanic rock to form soil, enabling seeds to germinate. The possible sources of immigrants were the mainland areas of Java and Sumatra, both approximately 40 km away, and two small islands, 12 and 20 km away (Figure 3(a)). More precise identification of the sources for colonization in Krakatau by the methods applied thus far is highly speculative. Furthermore, most species were discovered after they had already established populations, with no data on their actual arrival; obviously, there are very few data on arrivals not followed by recruitment. Yet, even with these restrictions, the main insights from this unique long-term classical case study are extremely important; Thornton's (1996) book tells the story of the reassembly of this island ecosystem.

The immigration data collected on Krakatau, albeit incomplete, provide important information on the dispersal process itself. One of the most important modes of dispersal was by sea, whether passively (e.g., fruits and seeds) or actively (e.g., the water monitor *Varanus salvator*). There was a striking example of rafting (Box 1) in a 20-m²-area floating island with 3–4-m high palms observed in the archipelago in 1986. Dispersal by air, either passively (spores, light seeds, and other aerial plankton) or actively (butterflies, birds, and bats), was another important mode. Birds and bats served as dispersal agents for plant seeds over short (within the archipelago) and long (from the mainland to the archipelago) distances.

One of the most remarkable patterns observed in the Krakatau system is that of unequal colonization. This pattern was largely clarified for plants when dispersal agents were classified into three primary types (wind, sea, and animals) and examined in three time phases since the eruption (Figure 3(b)). Sea-dispersed species were the most important early colonizers but became the least important by the third phase; animal-dispersed species generally showed the opposing trend; the relative importance of wind-dispersed species remained fairly constant in all phases. The mode of dispersal also explains why several kinds of taxa were underrepresented. Species with large and heavy seeds dispersed either by wind (wings) or by bats and terrestrial mammals (Figure 3(c)). Moreover, some species reached, but did not colonize, the archipelago. Over the period of 8 years (1984–1992), 54 species of animals were recorded as new arrivals to Anak Krakatau (a small island in the center of the archipelago, which emerged from the sea in 1928; Figure 3(a)). Fourteen were new to the archipelago, whereas more than 20 did not establish. The absence of several sea-dispersed plant species is attributed to postdispersal conditions. The role of establishment conditions is also reflected in the decrease of the colonization rate with increasing species richness.

Removal of Barriers

Dissolution of barriers is typically accompanied by species invasion in both directions. Although the term “biotic interchange” might be interpreted as a balanced exchange, the pattern is often highly asymmetric. Climatic changes and tectonic plate movements in geological times have repeatedly created and destroyed dispersal barriers, and both kinds of events have had important biogeographic and evolutionary consequences (Figure 2). Such events include the closure of

(a)

(b)

(c)

the Tethyan seaway and the formation of a wide land bridge between Africa and Asia during the Miocene Epoch 18 million years ago (Ma). Likewise, the reoccurring Bering land bridge and strait have intermittently served as a dispersal route between the terrestrial biota of northeastern Asia and northwestern North America, and between the marine biota of the north Pacific and Arctic–Atlantic basins. Another well-studied example is the current land bridge between South and North Americas, which was formed 3.5 Ma; it provided a dispersal route for a massive passage – the Great American Interchange – of terrestrial organisms, and a dispersal barrier for the marine biota of the Atlantic and Pacific oceans. These examples demonstrate how dispersal and vicariant events can take place simultaneously.

Since the fossil record of mammals is richer than that of other vertebrates, the passage of mammals during the Great American Interchange has been the most thoroughly documented. It is clearly asymmetric, with many more North American taxa passing through the filter and diversifying in South America than the converse. In other terrestrial vertebrates, however, the interchange was either roughly balanced (e.g., birds) or biased in the opposite direction – that is, predominantly from south to north (reptiles, amphibians, and even freshwater fishes). Indeed, the differential response to the creation of the land bridge shows large variation also at lower taxonomic levels; in general, most taxa in both continents actually did not expand their ranges to the other continent.

Of the several episodes of biotic interchange that have occurred recently, perhaps the one most intensively studied is that through the Suez Canal, which connects the Mediterranean Sea to the Red Sea. Before the canal was opened for navigation in 1869, only a very few euryhaline species were able to cross the hypersaline lakes that have occasionally connected the two seas (Por, 1978). The creation of the Suez Canal led to an almost unidirectional colonization named Lessepsian migration after Ferdinand de Lesseps, the designer and chief constructor of the canal. It involves the colonization of the Mediterranean by at least 120 mollusks, 70 crustaceans, and more than 80 fish species from the Red Sea. Two main explanations for the unidirectional colonization have been proposed. The first, that species from the Gulf of Suez, the saline arm of the Red Sea at the southern end of the canal, were better preadapted physiologically to cross the hypersaline canal and lakes than were species from the northern end of the Mediterranean. The second postulates that species from the more diverse biota of the Red Sea are superior in competition, defense, or reproduction to species of the impoverished biota of the eastern Mediterranean. A similar explanation has also been raised to explain the asymmetry in the passage of mammals during the Great American Interchange. Comparisons between species that colonize and closely related

species that do not colonize show, in general, a tendency for r-selection attributes (see Preadaptations) among colonizers, especially higher dispersal ability and fast growth.

Natural Range Expansion

Recent Range Expansion

Well-documented major range expansions provide a unique opportunity to quantify and model the process of spatial spread at large scales. Charles Elton (1900–1991) and John G. Skellam (1914–1979) laid the foundations for the dynamic progress recently experienced in this field. Most range expansions at present are related to human activity (see The Spread of Alien Species), but some that are presumably natural range expansion are of particular interest to explore how species expand their range without human-aided transportation (see Hengeveld, 1989; Shigesada and Kawasaki, 1997; Williamson, 1996).

Range expansion can be very abrupt and may be followed by a rapid contraction, a phenomenon called boom-and-bust (Williamson, 1996). The most remarkable examples are three African locusts (*Schistocerca gregaria*, *Locusta migratoria*, and *Nomadacris septemfasciata*), which usually inhabit limited areas, but which reproduce rapidly, change their morphology and behavior, and disperse in huge swarms to forage over much larger areas under particularly favorable weather and food conditions. Populations of several rodent species such as lemmings (*Lemmus* spp.) also exhibit marked (cyclic) fluctuations, but due to their lower dispersal capacities, the resulting geographical impact is much more limited. Typically, these outbreaks do not result in expanding the breeding distribution of these species, as occasionally occurs after outbreaks of some bird species such as crossbills (*Loxia curvirostra*) and Pallas' sandgrouse (*Syrhaptes paradoxus*).

The accidental occurrence of individuals far away from the breeding sites has been documented in many taxa, especially in volant animals. For example, in 1979, the author observed an accidental arrival to Elat (southern Israel) of a female long-tailed duck (*Clangula hyemalis*) whose southernmost breeding and wintering regions in Europe are in Sweden and northern France, respectively. Fifteen months later, at the very same salt pond, the author collected an exhausted shy albatross (Box 1), a rare seabird that breeds on islands near Tasmania and New Zealand. Some accidental vagrants may establish viable populations (jump range expansion), as did the purple gallinule (*Gallinula martinica*), a colorful waterfowl, in the Tristan da Cunha Islands at the Mid-Atlantic Ridge after years as a vagrant visitor. This tropical species has been reported as a rare vagrant as far north as Nova Scotia in Canada.

Events of boom-and-bust and of vagrant occurrence illustrate three important points: first, that species differ in their dispersal ability (see Mechanisms and Adaptations for

Figure 3 Colonization of plant species to the Krakatau archipelago between Sumatra and Java (a). The number of species colonizing the island of Rakata increased over the period 1883–1989. Species with different primary dispersal mechanisms (sea, animal, and wind) exhibit dissimilar colonization dynamics more than three phases of this period (b). A model of island colonization derived from these empirical data (c) incorporates the dispersal mechanisms and temporal phases with a distinction between strand-line (outer circle) and interior habitats, and emphasizes colonization constraints (the lower right figure). Arrow widths are proportional to the cumulative number of species in species per year (values are given by each arrow). Reproduced from Bush MB and Whittaker RJ (1991) Krakatau: colonization patterns and hierarchies. *Journal of Biogeography* 18: 341–356, with permission from Blackwell Science Ltd, and Whittaker RJ and Jones SH (1994) Structure in re-building insular ecosystems: An empirically derived model. *Oikos* 69: 524–530, with permission from Wiley.

Dispersal; **Box 1**); second, that the current breeding distributions of these species is not limited by dispersal *per se* (see Physical Access: Dispersal Barriers and Dispersal Routes); and third, that postdispersal factors are important determinants of colonization success (see Ecological Opportunity: Postdispersal Establishment). However, these events are episodic and, thus, difficult to study. In contrast, some persistent cases of recent broad-scale range expansions that have been documented in detail are important contributions to the study of dispersal and population spread. As in the previous case, the best examples come from highly mobile animals. One well-studied case is the collared dove (*Streptopelia decaocto*), which, since 1900, has expanded its range from Turkey through the Balkans to the rest of Europe. Another is the cattle egret (*Bubulcus ibis*), which expanded its range in all continents since the late 1800s. It naturally colonized South America from its breeding grounds in Africa by the mid-1930s (jump range expansion) and rapidly expanded throughout the New World. For a more detailed discussion of range expansion, see The Spread of Alien Species and Modeling.

Holocene Postglacial Spread

The considerable fluctuations in the global climate during the Pleistocene (the geological epoch between 1.8 Ma and 11 thousand years ago (Ka)) have led to several glacial–interglacial cycles. The last glacial period reached its maximum about 18 Ka, when ice sheets covered extensive parts of Eurasia and North America. Species responded in various independent ways, depending on their physiology, life history strategies, and dispersal abilities. Many species were able to track the shift of their most favorable climate and habitats, experiencing range contraction or range shift southward. From about 15 Ka, the climate warmed, the ice retreated, and species expanded their range northward from refugia. Valuable data on this range expansion during the Holocene (the last 11,000 years) come from insect exoskeletons, plant macrofossils, and pollen cores collected from many localities. Analyses of genetic diversity provide another important source of information about patterns of postglacial spread.

The postglacial expansion of trees in North America and Europe has been studied extensively based on fossil pollen cores from lake sediments across a wide geographical range, dated by radiocarbon (^{14}C) analysis. The results are often expressed as isochrone maps in which contours join sites where similar pollen-stratigraphical events occurred at the same time, and as rates of range expansion during a given period (**Table 1**). These interpretations, however, should be made with care since pollen of many tree species are effectively dispersed over large distances; pollen data also contain a nonlocal component. Estimation of this component is possible through data on other plant remains (seeds, fruits, leaves, twigs, wood), the so-called plant macrofossils, that are less likely to be transported over large distances. The relatively few studies in which macrofossils have been well documented showed that the main conclusions based on pollen data alone were fairly robust. Yet, recent genetic and macrofossil studies cast doubts about the generality of these conclusions, revealing the existence of cryptic higher latitude refugia for a variety of plant and animal species.

The paleoecological pollen record shows an individualistic response of tree species, in the timing, direction, and speed of their spread. This variation can be partially explained by factors other than dispersal; for example, the existence of small cryptic high latitude refugia reasonably indicates adaptations to survive in cold environments. Yet, the paleoecological evidence also shows that species were able to cross dispersal barriers as large as the North American Great Lakes, the English Channel, and the Baltic Sea. In particular, it provides evidence that range expansion of trees can be very rapid with estimated average rates of spread of a few hundred meters per year (**Table 1**) and more. These estimated rates greatly exceed the rates expected from the observed dispersal rates of these species, collected at ecological spatial and temporal scales (see The Evolutionary and Population Genetics Perspectives). The discrepancy has been a long-standing puzzle for plant ecologists, termed Reid's paradox after Clement Reid who described it for British oaks. Even more puzzling than the rate of expansion of oaks – whose acorns may occasionally be dispersed over large distances by birds – is the rapid rate of expansion of woodland herbs that mostly propagate clonally and possess no obvious mechanism for LDD (Cain *et al.*, 1998). Indeed, the existence of cryptic high latitude refugia suggests that for those species postglacial spread rates were much slower than those inferred from the fossil pollen record.

The discussion of Reid's paradox has recently been revived because of the need to predict biological responses to human-induced climate warming. In fact, evidence on population expansions of a variety of plants and animals (Parmesan and Yohe, 2003) indicate that global climatic warming is already reflected in considerable poleward shift of species' distributions. Consequently, scientists have developed new mathematical models for seed dispersal that incorporate the long-distance component as well (see Modeling). The next step is development of frameworks capable of incorporating projected scenarios of dispersal, demographic and environmental changes into spread models to predict species spread in future environments. A recent example applied to predict the future spread rates of North American wind-dispersed tree species showed that spread rates on the order of $> 50 \text{ m yr}^{-1}$ are very unlikely under most conditions and for most species (Nathan *et al.*, 2011a).

Another advance in the study of postglacial range expansion follows the progress in molecular genetics that enables assessment of present genetic structure; that is, in turn, used to infer past colonization events (see Inference from Current Distributions). Godfrey Hewitt (1999) summarized the results of studies dealing with the postglacial colonization of the European biota (both animals and plants) from three main refugia at the eastern (Balkans), central (Italian), and western (Iberian) peninsulas of southern Europe. He proposed three main expansion patterns, which were termed, after their exemplars, “hedgehog,” “grasshopper,” and “bear” (**Figure 4(c)**): the hedgehog (*Erinaceus* spp.) expanded with three genomes advancing north from the three refugia; the grasshopper (*Chorthippus parallelus*) colonized mostly from a eastern refugium, with other genomes blocked at the Pyrenees and Alps; the bear (*Ursus arctos*) colonized from the east and the west, with its central refugium blocked at the Alps.

^aPostglacial expansion rates of trees during the late Quaternary, based on fossil pollen records. The first row in each data set shows the overall average rate during the entire period examined, the second row shows the period with the fastest rate, the third shows data from the same period (in North America and British Isles separately), for comparison.

Figure 4 Postglacial recolonization of European biota. The physical geography of Europe (a) is characterized by mountain ranges running from the Pyrenees eastward through the Alps to Caucasus, marked as black regions (>2000 m) and dashed lines (>1000 m altitude). By the end of the Pleistocene ice age (b) extensive ice sheets (hatched) covered northern Europe, and a permafrost plain extended southward to the mountain ranges. The rapid postglacial expansion from the three southern peninsular refugia (c), as deduced from molecular data and fossil evidence, followed three main patterns as illustrated by four examples in each column (see text for details). Reproduced from Hewitt GM (1999) Postglacial re-colonization of European biota. *Biological Journal of the Linnean Society* 68: 87–112, with permission from Wiley.

Spread of Early Hominins

Modern man (*Homo sapiens sapiens*) is currently the species with the most widespread geographical distribution, and other globally distributed species are mostly human commensalists. The dispersal biogeography of humanity is a very intriguing subject; it is also an excellent case study that demonstrates many essential aspects of dispersal biogeography. The following discussion briefly summarizes the patterns of dispersal and range expansion of early hominins (note that there still is some argument over this topic).

The ancestral source location of early hominins is considered to be the plains of the eastern Rift Valley in Africa (now Ethiopia, Kenya, and Tanzania) where fossils of early, woodland-dwelling, hominins were found (*Ardipithecus kadabba*, 5.8–5.5 Ma, *Ardipithecus ramidus*, 4.5–4.3 Ma, *Australopithecus anamensis*, 4.2–3.9 Ma, and *Australopithecus afarensis*, 3.6–2.9 Ma). The cooling period during the Middle Pliocene (3.0–2.4 Ma) marks the emergence and dispersal of the genus *Homo*. The traditional hypothesis postulates that the earliest *Homo* species, omnivorous scavengers who lived in open habitats between 2.5 and 2.0 Ma, shifted from forests to open landscapes, like many other mammalian species, in response to expanding dry savannah. An alternative hypothesis emphasizes the behavioral and phenotypic plasticity of early hominins, enabling them to cope with environmental changes and a variety of habitats, rather than a particular environment. Two well-documented *Homo* species, *H. habilis* (since ~2.3 Ma) and *H. erectus* (since ~1.95 Ma), and possibly other *Homo* species such as *H. ergaster* coexisted in the African Rift Valley until ~1.4 Ma. The *H. erectus/ergaster* type (also called the erectine group) had a long torso and limbs, narrow hips, a large brain, reduced dentition, and elementary stone

technology. The findings of much bone and stone refuse near lakes and streams suggest that early hominins congregated within catchment basins and utilized local resources until they were exhausted, and then moved to another catchment, and so on. All of these attributes served as morphological and behavioral preadaptations (see Preadaptations) for successful dispersal to and colonization of similar habitats outside Africa during the Pliocene (Figure 5). It has long been hypothesized that humans and certain animals (e.g., large bovids) emerged and dispersed together in response to environmental changes. Recent studies, however, emphasize the role of tool production and socialization, which enabled early hominin groups to succeed in a broad range of environmental conditions, as the key features leading to earliest dispersals out of Africa.

Among the earliest fossils of *Homo* found outside Africa, those found in Dmanisi (Georgia), dated ~1.8 Ma and defined as a distinct species (*H. georgicus*), are currently considered the oldest reliable record of *Homo* outside Africa. *Homo georgicus* was a short bipedal hominin with a small brain and, overall, a very primitive morphology resembling both *H. habilis* and erectines. The dating of early erectine skulls found in Mojokerto and Sangiran (Java, Indonesia) is still controversial with estimates ranging from 1.8 to 1.2 Ma for the former and 1.7 to 1.0 Ma for the latter. Skull remains found in Ubeidiya (Israel) are dated 1.4 Ma. The Dmanisi and Ubeidiya sites are rich with lithic artifacts and faunal remains assumed to be indicative of hominin presence; similar findings were also reported from Renzidong (China, 2.5–2.0 Ma) and Riwayat (Pakistan, 2.4–1.9 Ma) and from Erq-el-Ahmar (Israel), Pabbi hills (Pakistan), and Longgupo (China), all dated 1.95–1.77 Ma. Thus, the first departure from Africa occurred

Figure 5 Dispersal routes that allowed passage from Africa across the Middle-East into South and East Asia during the late Pliocene and the main sites where human remains were discovered.

about 2 Ma, perhaps even earlier. During this period, there were wide land bridges between Africa and Eurasia at the Sinai Peninsula, and at the straits of Bab-el-Mandab between the Red Sea and the Indian Ocean. Probably both served as dispersal routes for *Homo*. Since this early departure from Africa 2 Ma, early hominins successively dispersed from Africa to Asia, and later to Europe, where the earliest *Homo* fossil found (in Atapuerca hills, Spain) is dated 1.2 Ma. Evidence shows that *Homo sapiens*, our own species, also originated in Africa from where it eventually colonized a much broader range than any of its extinct predecessors.

The Spread of Alien Species

Humans can facilitate the physical access of organisms from one region to another by breaking dispersal barriers or by providing dispersal routes. Species that have colonized non-native regions due to human activities are called alien species, and those that have been deliberately transferred are called introduced species. Many closely related terms, including adventive, exotic, and invasive species, have been used

confusingly in the literature. Though examples are numerous, the spread of alien species represents merely a small, though growing, fraction of the total number of incidents in which humans have intentionally or accidentally facilitated physical access. Further, as a general rule – termed “propagule pressure” by Mark Williamson (1996), which is principally equivalent to the rescue effect (see Extinction) – single or very few propagules are unlikely to invade. Increasing the number of propagules (e.g., by repeated introduction attempts) increases the chance of an alien species to establish and spread.

The literature provides a wide array of case studies of various taxa across the entire globe, from zebra mussels and starlings in North America to rabbits and myxoma virus in Australia (Table 1). Here the classical case study of the muskrat (*Ondatra zibethicus*) has been chosen to illustrate the implications from such events to dispersal biogeography.

The muskrat is a large semiaquatic rodent native to North America (Figure 6). In 1905, five muskrats escaped from a fur-breeding farm near Prague in Czechoslovakia. Within 50 years, their descendants and others inhabited large parts of the

Figure 6 The spread of muskrats in central Europe, showing boundaries of apparent expansion for various years. Reproduced from Figures 4.3 and 4.4 in Williamson M (1996) *Biological Invasions*. Dordrecht, Boston, London: Kluwer Academic Publishers, with permission from Springer.

European continent (Figure 6), despite eradication programs initiated due to muskrat damage to roads, dikes, and agriculture. Expansion of the muskrat appeared to be rapid and of constant rate (*see* Reproduction–Dispersal Models for quantification of this case study). At finer scales, however, expansion was fairly variable in space and, to a lesser extent, in time (Table 1). Overall, the expansion was closely related to the geographical structure of the species' favorable wet habitats. River valleys, one kind of favorable habitat, provided dispersal routes, whereas mountain ranges acted as dispersal barriers, forming a starlike expansion pattern. Interestingly, favorable habitats do not necessarily increase, but may also decrease the rate of spread, as happened in regions with abundant wet habitats where muskrats settled and built up huge populations. Understanding the interplay between the processes of dispersal and of population growth is critical to the understanding of range expansion (*see* Modeling). Temporal changes should also be taken into account, since expansion rates were lower in dry years when the species' favorable habitats were more restricted.

Inference from Current Distributions
